Multiuser Wireless Power Transfer via Magnetic Resonant Coupling: Performance Analysis, Charging Control, and Power Region Characterization

Mohammad R. Vedady Moghadam, Student Member, IEEE, and Rui Zhang, Senior Member, IEEE

Abstract

Magnetic resonant coupling (MRC) is an efficient method for realizing the near-field wireless power transfer (WPT). Although the MRC enabled WPT (MRC-WPT) with a single pair of transmitter and receiver has been thoroughly studied in the literature, there is limited work on the general setup with multiple transmitters and/or receivers. In this paper, we consider a point-to-multipoint MRC-WPT system with one transmitter delivering wireless power to a set of distributed receivers. We aim to introduce new applications of signal processing and optimization techniques to the performance characterization and optimization in multiuser WPT via MRC. We first derive closed-form expressions for the power drawn from the energy source at the transmitter and that delivered to the load at each receiver. We identify a "near-far" fairness issue in multiuser power transmission due to receivers’ distance-dependent mutual inductance with the transmitter. To tackle this problem, we propose a centralized charging control algorithm to jointly optimize the receivers’ load resistance to minimize the total transmitter power drawn while meeting the given power requirement of each load. For ease of practical implementation, we also devise a distributed algorithm for the receivers to adjust their load resistance independently in an iterative manner. Last, we characterize the power region that constitutes all the achievable power-tuples of the loads with their adjustable resistance. In particular, we compare the power regions without versus with the time sharing of users’ power transmission, where it is shown that time sharing yields a larger power region in general. Extensive simulation results are provided to validate our analysis and corroborate our study for the multiuser MRC-WPT system.

I. INTRODUCTION

Inductive coupling [2], [3] is a conventional method to realize the near-field wireless power transfer (WPT) for short-range applications in centimeters. Recently, magnetic resonant coupling (MRC) [4]-[7] has drawn significant

This paper will be presented in part at IEEE International Conference on Acoustics, Speech, and Signal Processing (ICASSP), Brisbane, Australia, April 19-24, 2015 [1].

R. Zhang is with the Department of Electrical and Computer Engineering, National University of Singapore (e-mail: elezhang@nus.edu.sg). He is also with the Institute for Infocomm Research, A*STAR, Singapore.
interests for implementing the near-field WPT due to its high power transfer efficiency and yet longer operation range, say, up to a couple of meters. Furthermore, MRC effectively avoids the power leakage to non-resonant externalities and thus ensures safety to neighboring environment.

Two different methods are commonly adopted in practice to implement MRC enabled WPT (MRC-WPT). In the first method [4], [5], resonators, each of which is a tunable RLC circuit, are placed in close proximity of the electromagnetic (EM) coils of the energy transmitter and receiver to efficiently transfer power between them. Since resonators are designed to resonate at the system’s operating frequency, the total reactive power consumption in the system is effectively minimized at resonance and hence high power transfer efficiency is achieved over longer distance as compared to conventional inductive coupling. In the second method [6], [7], series and/or shunt compensators, each of which is a capacitor with variable capacity, are embedded in the electric circuits of energy transmitter and receiver with their natural frequencies set same as the system’s operating frequency, to achieve resonance. Generally speaking, the second method achieves higher power transfer efficiency over the first method, since in the first method resonators incur additional power loss due to internal ohmic resistance. However, the electric circuits of energy transmitters and receivers need to be accessible in the second method to embed compensators in them.

It is worth nothing that the MRC-WPT system with a single pair of transmitter and receiver has been extensively studied in the literature, with the aims such as maximizing the end-to-end power transfer efficiency or the power delivered to the receiver’s load with a given input power [8]–[11]. However, there has been limited work on analyzing the performance of MRC-WPT system under the general setup with multiple transmitters and/or receivers. The system with two transmitters and a single receiver or that with a single transmitter and two receivers has been studied in [12]–[16], while their results cannot be directly applied to the system with more than two transmitters/receivers. The multipoint-to-point system has been recently investigated in [17], while the interactions between the energy transmitters and receiver were demonstrated only through simulations. To our best knowledge, there has been no prior work on rigorously establishing a mathematical framework to jointly design the parameters in multi-transmitter/receiver MRC-WPT systems for performance optimization, which thus motivates our work.

In this paper, we consider a point-to-multipoint MRC-WPT system based on the series compensator method aforementioned, as shown in Fig. 1 where one transmitter that is connected to a stable energy source supplies wireless power to a set of distributed receivers. Each receiver is connected to an electric load via a switch, where the switch connects/disconnects the load to/from the receiver. We aim to apply signal processing and optimization techniques to the performance characterization and optimization in multiuser MRC-WPT system. First, by extending
the results in [12]–[17], we derive closed-form expressions for the power drawn from the energy source at the transmitter and that delivered to the load at each receiver, in terms of mutual inductance among the transmitter and receivers as well as their circuit parameters, for arbitrary number of receivers. Our results reveal a near-far fairness issue in multiuser wireless power transmission, similar to its counterpart phenomenon in multiuser wireless communication. Specifically, a receiver that is far from the transmitter and thus has a small mutual inductance with the transmitter receives lower power as compared to a receiver that is closer to the transmitter, with other circuit parameters given identical. We thus propose to mitigate the near-far issue by jointly designing the receivers’ load resistance to control their received power by exploiting the mutual coupling effect in the MRC-WPT system. This is analogous and yet in sharp contrast to the method of adjusting antenna weights at the transmitter to control the received power at different receivers in the existing far-field microwave or radio frequency (RF) transmission enabled WPT [18], [19].

To achieve this goal, we consider the scenario where a central controller is equipped at the transmitter to coordinate the multiuser power charging, by assuming that it has the full knowledge of all receivers, including their circuit parameters and power requirements. The central controller jointly designs the adjustable load resistance of all receivers to minimize the total power consumed at the transmitter subject to the given minimum power requirement of each load. For ease of practical implementation, we also consider the scenario without any central controller installed and devise a distributed algorithm for charging control by adjusting the loads’ resistance at their individual receivers in an iterative manner. In the distributed algorithm, each receiver sets its load resistance independently based on its local information and a one-bit feedback shared by each of the other receivers, where
the feedback of each receiver indicates whether the received power of its load exceeds the required power level or not. It is shown via simulations that the distributed algorithm achieves performance very close to the optimal solution by the centralized algorithm with a finite number of iterations.

Last, we characterize the power region for multiuser power transfer which constitutes all the achievable power-tuples of the receivers’ loads given their adjustable resistance. Specifically, we introduce the time-sharing based multiuser power transfer, where the transmission is divided into orthogonal time slots and within each time slot only a selected subset of receivers are scheduled to receive power, while the other receivers are disconnected from their loads. This is aimed to more effectively control the mutual coupling effect between the transmitter and receivers in WPT. It is shown that time sharing can enlarge the power region over the case without time sharing. It is also shown that time sharing can further mitigate the near-far issue by allocating more time to receivers that are more far-away from the transmitter. Furthermore, we revise the centralized multiuser charging control algorithm for the case without time sharing to jointly optimize the time allocation and load resistance for all the receivers in the case with time sharing, to further reduce the transmitter power consumption under the same average power requirement of each load.

The rest of this paper is organized as follows. Section II introduces the system model. Section III presents our analytical results. Section IV presents both the centralized and distributed multiuser power charging control algorithms. Section V characterizes and compares the power regions without versus with time sharing. Finally, we conclude the paper in Section VI.

II. SYSTEM MODEL

As shown in Fig. 1, we consider an MRC-WPT system with a single transmitter and \( N \geq 1 \) receivers, indexed by \( n, n \in \mathcal{N} = \{1, \ldots, N\} \). The transmitter and receivers are equipped with EM coils for realizing wireless power transfer, while an embedded communication system is assumed to enable information sharing among them. The transmitter is connected to a stable energy source supplying sinusoidal voltage over time given by \( \tilde{v}_{tx}(t) = \text{Re}\{v_{tx}e^{jwt}\} \), with \( v_{tx} \) denoting a complex voltage which is assumed to be constant, and \( w > 0 \) denoting its operating angular frequency. Each receiver \( n \) is connected via a switch to a given electric load (e.g. battery charger), named load \( n \), with resistance \( x_n > 0 \). The switch is used to connect/disconnect each load to/from its corresponding receiver. The state of switch at each receiver \( n \) is given by \( s_n \in \{0, 1\} \), where \( s_n = 1 \) and \( s_n = 0 \) denote the open and closed state, respectively.

1 As an example, the alliance for wireless power (A4WP) specification [20] uses a low energy profile Bluetooth network at the band of 2.4GHz for communication and system control, which aims to schedule the charging sequence of receivers and also control their individual charging power according to the given priorities.
switch is closed and open, respectively. It is also assumed that the transmitter and each receiver \(n\) are compensated by series capacitors with capacities \(c_{tx} > 0\) and \(c_n > 0\), respectively.

Let \(\tilde{i}_{tx}(t) = \text{Re}\{i_{tx}e^{jwt}\}\), with complex \(i_{tx}\), denote the steady state current flowing through the transmitter. This current produces a time-varying magnetic flux in the transmitter’s EM coil, which passes through nearby receivers’ EM coils and induces time-varying currents in them. We denote \(\tilde{i}_n(t) = \text{Re}\{i_ne^{jwt}\}\), with complex \(i_n\), as the steady state current at receiver \(n\). It is worth pointing out that the magnetic flux is the main medium of wireless power transfer considered in this paper, while the electric field is evanescent and thus is ignored \[4\]. This is in contrast to the RF based far-field WPT \[18\], \[19\], where the synchronized oscillations of magnetic and electric fields radiate energy in the form of EM waves propagating through the environment.

We denote \(r_{tx} > 0\) (\(r_n > 0\)) and \(l_{tx} > 0\) (\(l_n > 0\)) as the internal resistance and the self-inductance of the EM coil of the transmitter (receiver \(n\)), respectively. We also denote the mutual inductance between EM coils of the transmitter and each receiver \(n\) by \(h_n > 0\), with \(h_n \leq \sqrt{l_n l_{tx}}\), where its actual value depends on the physical characteristics of the two EM coils, their locations, alignment (or misalignment) of oriented axes with respect to each other, the environment magnetic permeability, etc. For example, the mutual inductance of two coaxial circular loops that lie in the parallel planes with separating distance of \(d\) meter is proportional to \(d^{-3}\) \[21\]. Moreover, since the receivers usually employ smaller EM coils than that of the transmitter due to practical size limitation and they are also physically separated, we ignore the mutual inductance between any pair of them for simplicity.

The equivalent electric circuit model of the considered MRC-WPT system is also shown in Fig. 1, in which the natural angular frequencies of the transmitter and each receiver \(n\) can be expressed as

\[
\omega_{\text{natural,tx}} = \frac{1}{\sqrt{l_{tx} c_{tx}}} \quad \text{and} \quad \omega_{\text{natural,n}} = \frac{1}{\sqrt{l_n c_n}},
\]

respectively. We thus set the capacities of compensators’ capacitors as

\[
c_{tx} = \frac{1}{l_{tx} w^2}, \quad (1)
\]

\[
c_n = \frac{1}{l_n w^2}, \quad \forall n \in \mathcal{N}, \quad (2)
\]

so that the transmitter and all receivers have the same natural angular frequency as the voltage source’s angular frequency \(w\), i.e., \(\omega_{\text{natural,tx}} = \omega_{\text{natural,1}} = \ldots = \omega_{\text{natural,N}} = w\). We name \(w\) as resonant angular frequency.

In this paper, we assume that the transmitter and all receivers stay at fixed positions and the physical characteristics of their EM coils are \textit{a priori} known; thus, \(h_n, \forall n \in \mathcal{N}\), can be modeled as given constants. We also treat the load resistance \(x_n, \forall n \in \mathcal{N}\), as design parameters, which can be adjusted in real-time to control the performance of the MRC-WPT system based on the information shared among different nodes in the system, via the embedded communication system. Note that an electric load with any fixed resistance can be connected via
a rectifier in parallel with a boost (or triboost) converter to each receiver to realize an adjustable resistance [22]. Specifically, given the fixed input voltage, the on/off time intervals of the converter can be controlled in real time to change the average current flowing into the load, which is equivalent to adjusting the load resistance.

III. PERFORMANCE ANALYSIS

In this section, we present new analytical results on the performance of the MRC-WPT system with arbitrary number of receivers. A numerical example is also provided to validate our analysis and draw useful insights. Here, we assume that all receivers’ switches are closed, i.e., $s_n = 1$, $\forall n \in \mathcal{N}$; hence, the transmitter sends wireless power to all loads concurrently.

A. Analytical Results

By applying Kirchhoff’s circuit laws to the electric circuit model given in Fig. 1, we have

$$\left(r_{tx} + j \left( \frac{w l_{tx}}{w c_{tx}} - \frac{1}{w c_{tx}} \right) \right) i_{tx} - j w \sum_{k \in \mathcal{N}} h_k i_k = v_{tx}, \quad (3)$$

$$\left(r_n + x_n + j \left( \frac{w l_n}{w c_n} - \frac{1}{w c_n} \right) \right) i_n - j w h_n i_{tx} = 0, \quad \forall n \in \mathcal{N}. \quad (4)$$

From (1) and (2), we can set $w l_{tx} - 1/(w c_{tx}) = 0$ and $w l_n - 1/(w c_n) = 0$ in (3) and (4), respectively. This is due to the fact that the transmitter and all receivers are designed to resonate at same frequency $w$. By solving the set of linear equations given in (3) and (4), we can derive $i_{tx}$ and $i_n$’s as functions of the input voltage $v_{tx}$ as

$$i_{tx} = \frac{1}{r_{tx} + w^2 \sum_{k \in \mathcal{N}} h_k^2 (r_k + x_k)^{-1}} v_{tx}, \quad (5)$$

$$i_n = \frac{j w h_n (r_n + x_n)^{-1}}{r_{tx} + w^2 \sum_{k \in \mathcal{N}} h_k^2 (r_k + x_k)^{-1}} v_{tx}, \quad \forall n \in \mathcal{N}. \quad (6)$$

The power drawn from the energy source at the transmitter, denoted by $p_{tx}$, and that delivered to each load $n$, denoted by $p_n$, are then obtained as

$$p_{tx} = \frac{1}{2} \text{Re}\left( v_{tx} i_{tx}^* \right) = \frac{|v_{tx}|^2}{2} \frac{1}{r_{tx} + w^2 \sum_{k \in \mathcal{N}} h_k^2 (r_k + x_k)^{-1}}, \quad (7)$$

$$p_n = \frac{1}{2} x_n |i_n|^2 = \frac{|v_{tx}|^2}{2} \frac{w^2 h_n^2 x_n (r_n + x_n)^{-2}}{(r_{tx} + w^2 \sum_{k \in \mathcal{N}} h_k^2 (r_k + x_k)^{-1})^2}, \quad (8)$$

where $i_{tx}^*$ is the conjugate of $i_{tx}$. From (3), it follows that the power delivered to each load $n$ increases with the mutual inductance between EM coils of its receiver and the transmitter, i.e., $h_n$. This can cause a near-far fairness issue since a receiver that is far from the transmitter generally has a small mutual inductance with the transmitter; as a result, its received power is lower than that at a receiver that is closer to the transmitter (thus has a larger mutual inductance). Furthermore, we define $p_{sum} = \sum_{k=1}^{N} p_k$ as the sum-power delivered to all loads, where it can
be verified from (7) and (8) that $p_{\text{sum}} < p_{\text{tx}}$. The sum-power transfer efficiency, denoted by $0 \leq \rho < 1$, is thus expressed as

$$
\rho = \frac{p_{\text{sum}}}{p_{\text{tx}}} = \frac{w^2 \sum_{k \in \mathcal{N}} h_k^2 x_k (r_k + x_k)^{-2}}{r_{\text{tx}} + w^2 \sum_{k \in \mathcal{N}} h_k^2 (r_k + x_k)^{-1}}.
$$

**Remark 3.1:** When the receivers are all weakly coupled to the transmitter, e.g., they are sufficiently far away from the transmitter, we have $h_n \to 0$, $\forall n \in \mathcal{N}$. In this regime, from (7), it follows that the transmitter power is $p_{\text{tx}} \approx |v_{\text{tx}}|^2/(2r_{\text{tx}})$, which is a function of the resistance and voltage of the transmitter only. On the other hand, from (8), it follows that the power delivered to each load $n$ is $p_n \approx |v_{\text{tx}}|^2 w^2 h_n^2 x_n (r_n + x_n)^{-2}/(2r_{\text{tx}}^2)$, which is independent of the other receivers’ mutual inductance and resistance. The above results can be explained as follows.

With $h_n \to 0$, $\forall n \in \mathcal{N}$, the power transferred to the receivers is small and thus can be neglected as compared to the power loss due to the transmitter’s resistance. As a result, we have $p_{\text{tx}} \approx r_{\text{tx}} |i_{\text{tx}}|^2/2$, with $i_{\text{tx}} = v_{\text{tx}}/r_{\text{tx}}$. It also can be verified that with $h_n \to 0$, $\forall n \in \mathcal{N}$, the coupling effect among the receivers through the transmitter current $i_{\text{tx}}$ is negligible. Hence, the power delivered to the load at each receiver is independent of other receivers (similar to the far-field RF based WPT [18], [19]).

**Remark 3.2:** It can be shown from (8) that $p_n$, $\forall n \in \mathcal{N}$, first increases over $0 < w < \hat{w}$, and then decreases over $w > \hat{w}$, where

$$
\hat{w} = \sqrt{\frac{r_{\text{tx}}}{\sum_{k \in \mathcal{N}} h_k^2 (r_k + x_k)^{-1}}}.
$$

The above result can be explained as follows. From (6), it follows that the magnitude of the current flowing in each receiver $n$, i.e., $|i_n|$, strictly increases over $0 < w < \hat{w}$, but strictly decreases over $w > \hat{w}$. This yields that $w = \hat{w}$ is the unique maximizer of $|i_n|$ over $w > 0$. Obviously, $p_n$, which is defined in (8) as $p_n = x_n |i_n|^2/2$, behaves same as $|i_n|$ over $w > 0$. Although $w$ is assumed to be fixed in this paper, it can also be optimally set to maximize the system power transfer efficiency, if this is implementable in practice.

Next, we study the effect of changing the load resistance of one particular receiver $n$, i.e., $x_n$, on the transmitter power $p_{\text{tx}}$, its received power $p_n$, the power delivered to each of the other loads $m \in \mathcal{N}$, $m \neq n$, i.e., $p_m$, the sum-power delivered to all loads $p_{\text{sum}}$, and the sum-power transfer efficiency $\rho$, assuming that all the other loads’ resistance is fixed.

**Proposition 3.1:** $p_{\text{tx}}$ strictly increases over $x_n > 0$.

**Proof:** Please see Appendix A.

This result can be explained as follows. From (5), it is observed that the transmitter current $i_{\text{tx}}$ strictly increases over $x_n > 0$. Since the energy source voltage $v_{\text{tx}}$ is fixed, it follows that $p_{\text{tx}}$ given in (7) strictly increases over
\(x_n > 0.\)

**Proposition 3.2:** For each receiver \(m \neq n, n \neq m\), strictly increases over \(x_n > 0\). However, \(p_n\) first increases over \(0 < x_n < \hat{x}_n\), and then decreases over \(x_n > \hat{x}_n\), where

\[
\hat{x}_n = \frac{r_n(r_{tx} + \phi_n) + w^2 h_n^2}{r_{tx} + \phi_n},
\]

with \(\phi_n = w^2 \sum_{k \in \mathcal{N} \setminus \{n\}} h_k^2 (r_k + x_k)^{-1}\).

**Proof:** Please see Appendix B.

The above result can be explained as follows. From (6), it follows that for each receiver \(m, m \neq n\), its current \(i_m\) strictly increases over \(x_n > 0\). The received power \(p_m\) defined in (8) thus strictly increases over \(x_n > 0\). On the other hand, it follows from (6) that for receiver \(n\), its current \(i_n\) strictly decreases over \(x_n > 0\). However, from (8), it follows that the decrement in \(|i_n|^2\) is smaller than the increment of \(x_n\) when \(0 < x_n < \hat{x}_n\); therefore, \(p_n\) increases over \(x_n\) in this region. The opposite is true when \(x_n > \hat{x}_n\).

**Proposition 3.3:** If \(r_{tx} + \phi_n - 2 \varphi_n \leq 0\), \(p_{\text{sum}}\) strictly increases over \(x_n > 0\), where \(\varphi_n = w^2 \sum_{k \in \mathcal{N} \setminus \{n\}} h_k^2 x_k (r_k + x_k)^{-2}\); otherwise, \(p_{\text{sum}}\) first increases over \(0 < x_n < \check{x}_n\), and then decreases over \(x_n > \check{x}_n\), where

\[
\check{x}_n = \frac{r_n(r_{tx} + \phi_n) + w^2 h_n^2 + 2r_n \varphi_n}{r_{tx} + \phi_n - 2 \varphi_n}.
\]

**Proof:** Please see Appendix C.

This result is a consequence of Proposition 3.2 from which it is known that \(p_m\)'s, \(m \neq n\), strictly increase over \(x_n > 0\), while \(p_n\) first increases over \(0 < x_n < \hat{x}_n\) and then decreases over \(x_n > \hat{x}_n\). The sum-power \(p_{\text{sum}}\) can thus behave similar to either \(p_m\)'s (monotonically increasing) or \(p_n\) (initially increasing and then decreasing) over \(x_n > 0\), depending on the system parameters.

**Proposition 3.4:** If \(\varphi_n - \phi_n - r_{tx} \geq 0\), \(\rho\) strictly increases over \(x_n > 0\); otherwise, \(\rho\) first increases over \(0 < x_n < \check{x}_n\), and then decreases over \(x_n > \check{x}_n\), where

\[
\check{x}_n = \frac{-r_n \varphi_n - \sqrt{r_n^2 \varphi_n^2 - \Gamma_n}}{\varphi_n - \phi_n - r_{tx}},
\]

with 

\[
\Gamma_n = (\varphi_n - \phi_n - r_{tx})(r_n^2(r_{tx} + \varphi_n + \phi_n) + r_n w^2 h_n^2).
\]

**Proof:** Please see Appendix D.

This result is a consequence of Propositions 3.1 and 3.3 due to both behaviors of \(p_{tx}\) and \(p_{\text{sum}}\) over \(x_n > 0\).

### B. Validation of Analysis

For the purpose of exposition, we consider a point-to-multipoint MRC-WPT system with \(N = 3\) receivers, as shown in Fig. 2, where the transmitter and receivers use circular EM coils (see Fig. 11 in Appendix E), with
the physical characteristics given in Table I. Note that the transmitter and both receivers 2 and 3 lie in the plane with $z = 0$, while receiver 1 lies in the plane with $z = 0.91$ meter (m). Accordingly, the internal resistance and self-inductance of individual EM coils as well as the mutual inductance among them can be derived (see the details in Appendix E), where the obtained values are given in Table II. In this example, although all receivers use EM coils with the same physical characteristics, they are located in different distances from the transmitter. Specifically, receiver 1 is closest to the transmitter and thus has the largest mutual inductance with the transmitter, while receiver 3 is farthest and has the smallest mutual inductance. We set $v_{tx} = 20\sqrt{2}$V, and $w = 42.6 \times 10^6$rad/s
Fig. 3. Input and output power versus $x_1$. 

Fig. 4. The sum-power transfer efficiency $\rho$ versus $x_1$. 

(i.e., 6.78MHz), as suggested in the A4WP specification [20]. For this example, we fix $x_2 = x_3 = 2.5\Omega$. 

First, we plot $p_{tx}, p_n, \forall n \in N$, and $p_{sum}$ versus the resistance of load 1, i.e., $x_1$, in Fig. 3 It is observed that $p_{tx}, p_2, p_3$ and $p_{sum}$ all increase over $x_1 > 0$; however, $p_1$ initially increases over $0 < x_1 < \bar{x}_1 = 5.35\Omega$ and then declines over $x_1 > 5.35\Omega$. Note that in this example, the condition $r_{tx} + \phi_n - 2\varphi_n < 0$ holds in Proposition 3.3 The obtained results are all consistent with our above analysis. Last, we observe that varying $x_1$ not only changes $p_1$, but also the power delivered to other loads. For instance, receiver 1 can help receivers 2 and 3, which are farther away from the transmitter, to receive more power by increasing its load resistance $x_1$. This is a useful mechanism that will be utilized later in this paper to mitigate the near-far issue.

Next, in Fig. 4 we plot the sum-power transfer efficiency $\rho$ as a function of $x_1$. It is observed that $\rho$ follows a single-peak pattern over $x_n > 0$, i.e., it first increases over $0 < x_1 < \bar{x}_1 = 0.95\Omega$, and then smoothly declines.
over $x_1 > 0.95\Omega$. This result can be verified from Proposition 3.4 by considering the fact that in this example, the condition $\varphi_n - \phi_n - r_{tx} < 0$ holds. Note that when $x_1 \to \infty$, it follows from (5) and (7) that $i_1 \to 0$ and $p_1 \to 0$. This is equivalent to disconnecting load 1 from receiver 1, i.e., setting $s_1 = 0$. As a result, the efficiency converges when $x_1 \to \infty$, while the converged value depends on the parameters of the transmitter and the other two receivers.

IV. MULTIUSER CHARGING CONTROL OPTIMIZATION

In this section, we optimize the receivers’ load resistance $x_n$, for all $n \in \mathcal{N}$, to minimize the transmitter power $p_{tx}$ subject to the given load constraints, by assuming that $s_n = 1$, for all $n \in \mathcal{N}$, i.e., all the receive are connected to their loads. We first consider the case with a central controller at the transmitter, which has the full knowledge of all receivers, including their circuit parameters and load requirements, to implement centralized charging control. We then devise a distributed charging algorithm for the receivers to independently adjust their load resistance iteratively, for the ease of practical implementation. Last, we compare the performance of proposed algorithms.

A. Problem Formulation

We assume that in practice the resistance of each load $n$ can be adjusted over a given range $\underline{x}_n \leq x_n \leq \overline{x}_n$, where $\underline{x}_n > 0$ ($\overline{x}_n \geq \underline{x}_n$) is the lower (upper) limit of the resistance. It is also assumed that the power delivered to each load $n$ needs to be higher than a given minimum threshold $p_n > 0$ to guarantee its quality of service. Now, we formulate an optimization problem to minimize the transmitter power $p_{tx}$ subject to the given load constraints of all receivers as follows.

(P1): \[
\min_{\{\underline{x}_n \leq x_n \leq \overline{x}_n\}_{n \in \mathcal{N}}} \frac{|v_{tx}|^2}{2} \left( \frac{1}{r_{tx} + w^2 \sum_{k \in \mathcal{N}} h_k^2 (r_k + x_k)^{-1}} \right)
\text{s.t.} \frac{|v_{tx}|^2}{2} \left( \frac{w^2 h_n^2 x_n (r_n + x_n)^{-2}}{r_{tx} + w^2 \sum_{k \in \mathcal{N}} h_k^2 (r_k + x_k)^{-1}} \right)^2 \geq p_n, \forall n \in \mathcal{N}. \tag{14}
\]

Although (P1) is non-convex, we propose a centralized algorithm to solve it optimally in the next subsection.

B. Centralized Algorithm

First, based on (P1), we formulate the following (maximization) problem, of which the objective function is the inverse of that of (P1), and with the same constraints as (P1).

(P2): \[
\max_{\{\underline{x}_n \leq x_n \leq \overline{x}_n\}_{n \in \mathcal{N}}} \frac{2}{|v_{tx}|^2} \left( \frac{r_{tx} + w^2 \sum_{k \in \mathcal{N}} h_k^2 (r_k + x_k)^{-1}}{r_{tx} + w^2 \sum_{k \in \mathcal{N}} h_k^2 (r_k + x_k)^{-1}} \right)
\text{s.t.} \frac{|v_{tx}|^2}{2} \left( \frac{w^2 h_n^2 x_n (r_n + x_n)^{-2}}{r_{tx} + w^2 \sum_{k \in \mathcal{N}} h_k^2 (r_k + x_k)^{-1}} \right)^2 \geq p_n, \forall n \in \mathcal{N}. \tag{16}
\]
It can be verified that the optimal solution to (P2) also solves (P1); as a result, we can equivalently solve (P2) to derive the optimal solution to (P1). Although (P2) is still non-convex, we can re-formulate it as a convex problem by applying a change of variable. Specifically, we define a new set of variables as \( y_n = 1/(r_n + \bar{x}_n) \) and \( \bar{y}_n = 1/(r_n + \bar{x}_n) \). Accordingly, we rewrite (P2) as

\[
(P3): \max_{\{y_n \leq y_n \leq \bar{y}_n\}, n \in \mathcal{N}} \frac{2}{|v_{tx}|^2} \left( r_{tx} + w^2 \sum_{k \in \mathcal{N}} h_k^2 y_k \right) \\
\text{s.t.} \frac{|v_{tx}|^2}{2} w^2 h_n^2 (r_n y_n^* - y_n) + p_n \left( r_{tx} + w^2 \sum_{k \in \mathcal{N}} h_k^2 y_k \right)^2 \leq 0, \forall n \in \mathcal{N}. \tag{18}
\]

Note that (P3) is a convex optimization problem, with a linear objective function and linear/quadratic inequality constraints over \( y_n \)'s. As a result, (P3) can be efficiently solved using the existing software, e.g., CVX \[24\]. Let \((y_1^*, \ldots, y_N^*)\) denote the optimal solution to (P3). The optimal solution to (P2) is thus obtained by a change of variable as \( x_n^* = 1/y_n^* - r_n, \forall n \in \mathcal{N} \). The obtained \((x_1^*, \ldots, x_N^*)\) also solves (P1). The centralized algorithm to solve (P1) is summarized in Table III denoted by Algorithm 1. Since the feasibility of convex problem (P3) can be efficiently checked, in the rest of this paper, we assume that (P1), or equivalently (P3), is feasible without loss of generality.

\[\text{Table III}
\]

| Algorithm 1 |
|---------------|
| a) For each receiver \( n, \forall n \in \mathcal{N} \), given \( x_n > 0 \) and \( \bar{x}_n > x_n \), compute \( y_n = 1/(r_n + \bar{x}_n) \) and \( \bar{y}_n = 1/(r_n + x_n) \). Accordingly, formulate the problem (P3). |
| b) If (P3) is feasible, then save its optimal solution as \((y_1^*, \ldots, y_N^*)\). Set \( x_n^* = 1/y_n^* - r_n, \forall n \in \mathcal{N} \). Return \((x_1^*, \ldots, x_N^*)\) as the optimal solution to (P1). |
| c) If (P3) is infeasible, then it follows that there is no feasible solution to (P1) and thus the algorithm terminates. |

C. Distributed Algorithm

In this subsection, we present an alternative distributed algorithm for (P1), for the case without a central controller installed in the system. In this algorithm, each receiver adjusts its load resistance independently according to its local information and a one-bit feedback received from each of the other receivers indicating whether the corresponding load constraint is satisfied or not. We denote the feedback from each receiver \( n \) which is broadcasted to all other receivers as \( FB_n \in \{0, 1\} \), where \( FB_n = 1 \) \((FB_n = 0)\) indicates that its load constraint is (not) satisfied.

In Section III we show that the power delivered to each load \( n, p_n \), has two properties that can be exploited to adjust \( x_n \). First, \( p_n \) strictly increases over \( x_m > 0, \forall m \neq n \), which means that other receivers can help boost \( p_n \) by increasing their individual load resistance. Second, \( p_n \) has a single peak at \( x_n = \hat{x}_n \), assuming that all other load
Case 1: If $p_n(x_n^+) > p_n(x_n)$ and $p_n(x_n^-) < p_n(x_n)$, then $0 < x_n < \dot{x}_n$.

Case 2: If $p_n(x_n^+) < p_n(x_n)$ and $p_n(x_n^-) < p_n(x_n)$, then $x_n = \dot{x}_n$.

Case 3: If $p_n(x_n^+) < p_n(x_n)$ and $p_n(x_n^-) > p_n(x_n)$, then $x_n > \dot{x}_n$.

Now, we present the distributed algorithm in detail. The algorithm is implemented in an iterative manner, say, starting from receiver 1, where in each iteration, only one receiver $n$ adjusts its load resistance, while all the other receivers just broadcast their individual one-bit feedback $FB_m$, $m \neq n$, at the beginning of each iteration. Initialize $x_n = (r_n r_{tx} + w^2 h_n^2)/r_{tx}$, $\forall n \in N$, which is obtained from (11) by setting $\phi = 0$, i.e., assuming that all other receivers have their loads disconnected.\footnote{More precisely, in this case we have $\dot{x}_n - \Delta x \leq x_n \leq \dot{x}_n + \Delta x$.} At each iteration for receiver $n$, if $p_n < p_n$, then it will adjust $x_n$ to increase $p_n$. To find the direction for the update, the receiver needs to check for its current $x_n$ whether $0 < x_n < \dot{x}_n$, $x_n = \dot{x}_n$, or $x_n > \dot{x}_n$ holds, using the method mentioned above. On the other hand, if $p_n > p_n$, receiver $n$ can increase $x_n$ to help increase the power delivered to other loads when there exists any $m \neq n$ such that $FB_m = 0$ is received; or it can decrease $x_n$ to help reduce the transmitter power when $FB_m = 1$, $\forall m \neq n$.

In summary, we design the following protocol (with five cases) for receiver $n$ to update $x_n$.

Case 1: If $p_n < p_n$ and $0 < x_n < \dot{x}_n$, set $x_n \leftarrow \min\{x_n, x_n + \Delta x\}$.

Case 2: If $p_n < p_n$ and $x_n > \dot{x}_n$, set $x_n \leftarrow \max\{x_n, x_n - \Delta x\}$.

Case 3: If $p_n > p_n$, $x_n \neq \dot{x}_n$, and $\exists m \neq n$, $FB_m = 0$, set $x_n \leftarrow \min\{x_n, x_n + \Delta x\}$.

Case 4: If $p_n > p_n$, $x_n \neq \dot{x}_n$, and $FB_m = 1$, $\forall m \neq n$, set $x_n \leftarrow \max\{x_n, x_n - \Delta x\}$.

Case 5: Otherwise, no update occurs.

We set a maximum number of iterations, denoted by $itr_{\text{max}}$, after which the algorithm will terminate, regardless of whether it converges to any stable point $(x_1, \ldots, x_N)$ or not. However, when the algorithm terminates, in general there is no guarantee that the power constraints given in (11) hold for all loads. If constraint (15) holds for all loads, then the obtained $(x_1, \ldots, x_N)$ is generally a suboptimal solution to (P1); otherwise, it is infeasible for (P1).\footnote{This requires a protocol design so that when each new receiver is added in the system, its mutual inductance $h_n$ is measured and $x_n$ is accordingly computed and initially set at the receiver.}
TABLE IV  
DISTRIBUTED ALGORITHM FOR (P1).

Algorithm 2

a) Initialize $itr = 1$ and $itr_{\max} > 1$. Each receiver $n$ sets $x_n = \left(\frac{r_n r_{tx} + u^2 h_2^2}{r_{tx}}\right)$.

b) Repeat from receiver $n = 1$ to $n = N$:
   
   - Receiver $n$ collects $FB_m$ from all other receivers $m \neq n$.
   - Receiver $n$ updates its load resistance $x_n$ according Cases 1–5.
   - If $itr = itr_{\max}$, then quit the loop and the algorithm terminates.
   - Set $itr = itr + 1$.

Fig. 5. Performance comparison between centralized control (Algorithm 1) versus distributed control (Algorithm 2).

The distributed algorithm is summarized in Table IV as Algorithm 2.

D. Performance Comparison

We consider the same system setup as that in Section III-B. We set $x_n = 1\Omega$ and $x_n = 100\Omega$, $\forall n \in N$. We also set $p_1 = p_2 = 5$W, but vary $p_3$ over $0 < p_3 \leq 55.9$W, where (P1) can be verified to be feasible in this region. For Algorithm 2, we use $\Delta x = 10^{-3}$ and $itr_{\max} = 3 \times 10^5$, which is sufficiently large such that the algorithm converges to a stable point in our simulation.

Fig. 5 compares the transmitter power $p_{tx}$ obtained by both Algorithms 1 and 2 versus $p_3$. In this example, Algorithm 2 converges to a feasible solution to (P1) for all values of $p_3$. Furthermore, as shown in Fig. 5, Algorithm 2 achieves almost the same minimum $p_{tx}$ as that of Algorithm 1, which solves (P1) optimally, for all values of $p_3$.

Fig. 6 shows the convergence of Algorithm 2 under the above system setup with $p_3 = 50$W. It is observed that although $p_1 > p_1$ and $p_2 > p_2$ at the first iteration, we have $p_3 < p_3$. As a result, both receivers 1 and 2 help receiver 3 (which is most far-way from the transmitter) for receiving more power by lowering their received power levels via increasing their individual load resistance. It is also observed that this algorithm takes around $1.2 \times 10^5$
iterations to converge, since we use $\Delta x = 10^{-3}$ in the algorithm for updating $x_n$’s, which is a small step size to ensure smooth convergence. In practice, larger step size can be used to speed up the algorithm but at the cost of certain performance loss.

V. POWER REGION CHARACTERIZATION

In this section, we characterize the achievable power region for the receiver loads without versus with time sharing. First, we propose a time-sharing scheme to schedule multiuser power transfer by connecting/disconnecting loads to/from their receivers over time. We then propose a centralized algorithm to jointly optimize the time allocation and load resistance of receivers for time sharing based power transmission, by extending that for (P1) in Section IV for the case without time sharing. Last, numerical examples are provided to compare the power-region performance of the MRC-WPT system without versus with time sharing.

A. Multiuser Power Transfer with Time Sharing

As shown in Fig. 7, there are in general $Q = 2^N - 1$ time-sharing configurations for transferring power to $N$ receiver loads depending on the state of each receiver’s switch, which are indexed by $q, q \in Q = \{1, \ldots, Q\}$. Specifically, let $\mathcal{S} = \{(s_1, \ldots, s_N) \mid s_n \in \{0, 1\}, \forall n \in \mathcal{N}\}$ denote the set consisting of all possible states of receiver switches. Without loss of generality, we remove the trivial case that all switches are open, i.e., $s_n = 0,$
∀n ∈ N, from S by setting S ← S \ {(0, ..., 0)}. As a result, we have the cardinality of S as |S| = Q. For convenience, we assign an one-to-one mapping between the elements in the two sets Q and S, i.e., we assign each configuration q ∈ Q to one switch state (s₁, ..., sₙ) ∈ S. By default, we assign configuration q = 1 to (s₁, ..., sₙ) = (1, ..., 1), i.e., all switches are closed.

Let τ > 0 denote the total time available for power transmission. Let the time allocated for the power transmission under configuration q be denoted by τₗ, with 0 ≤ τₗ ≤ τ. We thus have ∑q∈Q τₗ ≤ τ, where the strict inequality occurs when the required energy, ∑ₗ τₗ, n = 1, ..., N, at all loads are satisfied by the end of Q-slot transmissions, where the voltage source at the transmitter can be switched off for the remaining time (τ − ∑q∈Q τₗ) > 0 to save energy.\footnote{Note that disconnecting all receivers from their loads, i.e. setting sₙ = 0, ∀n ∈ N, cannot achieve this goal, since the ohmic resistance of the transmitter circuit still consumes power as long as the transmitter voltage source is on.}

Over all configurations, the average transmitter power and the average power delivered to each load n can be obtained from (7) and (8), respectively, as follows:

\[ p_{tx} = \sum_{q \in Q} \frac{|v_{tx}|^2}{2\tau} \frac{1}{r_{tx} + w^2 \sum_{k \in N_q} h_k^2 (r_{k, q} - 1)^{-1} v_{tx}^2} \tau_q, \]  
\[ p_n = \sum_{q \in Q} \frac{|v_{tx}|^2}{2\tau} \frac{w^2 h_n^2 x_{n, q} (r_n + x_{n, q})^{-2}}{\left( r_{tx} + w^2 \sum_{k \in N_q} h_k^2 (r_{k, q} - 1)^{-1} \right)^2} \tau_q, \]

where \( x_{n, q} \) is the resistance value of load n under configuration q. Moreover, \( N_q \subseteq N \) denotes the subset of receivers with their loads connected under configuration q, while \( Q_n \subseteq Q \) denotes the subset of configurations under which receiver n has its load connected. Compared to the previous case without time sharing, the time allocation \( \tau_q, \forall q \in Q \), provides extra degree of freedom for the performance optimization.

**B. Power Region Definition**

The power region is defined as the set of power-tuples achievable for all loads with a given transmission time τ subject to their adjustable resistance values. Specifically, the power region for the case without time sharing (i.e., all loads receive power concurrently) is defined as

\[ R_{\text{without-TS}} = \bigcup_{\{0 \leq x_{n} \leq x_{n}\}_{n \in N}} (p_1, \ldots, p_N), \]  

with \( p_n, n \in N \), given in (8). Similarly, the power region for the case with time sharing is defined as

\[ R_{\text{with-TS}} = \bigcup_{\{0 \leq \tau_q \leq \tau\} \subseteq Q, \sum_{q \in Q} \tau_q \leq \tau} (p_1, \ldots, p_N), \]  

with \( p_n, n \in N \), given in (21). It is evident that the power region with time sharing is no smaller than that without time sharing, i.e., \( R_{\text{without-TS}} \subseteq R_{\text{with-TS}} \), since by simply setting \( \tau_1 = \tau \) and \( \tau_q = 0, \forall q \neq 1 \), we have \( R_{\text{without-TS}} = R_{\text{with-TS}} \).
C. Centralized Algorithm with Time Sharing: Revised

In this subsection, we extend the centralized algorithm in Section III without time sharing to the case with time sharing by jointly optimizing the time allocation and load resistance of all receivers to minimize the transmitter power subject to the given load (average received power) constraints. Thus, we consider the following optimization problem.

\[
(P4) : \min_{\{0 \leq \tau \leq \tau^*\} \in \mathbb{Q}, \{\mathbf{x}_{n,q}\} \in \mathbb{R}^n \times \mathbb{R}^q, \mathbf{w} \in \mathbb{R}^r} \sum_{q \in \mathbb{Q}} \frac{|v_{nx}|^2}{2\tau} r_{nx} + w^2 \sum_{k \in \mathbb{N}_q} h_k^2 (r_k + x_{k,q})^{-1} \tau_q
\]  
\[
\text{s.t. } \sum_{q \in \mathbb{Q}} \frac{|v_{nx}|^2}{2\tau} w^2 h_n^2 x_{n,q} (r_n + x_{n,q})^{-2} \tau_q \geq p_n, \forall n \in \mathcal{N}, \sum_{q \in \mathbb{Q}} \tau_q \leq \tau. \tag{25} \]

Although (P4) is non-convex, we can apply the technique of alternating optimization to approximately solve it, as discussed below. Since (P1) is assumed feasible, the feasibility of (P4) is ensured due to the fact that \(\mathcal{R}_{\text{without-TS}} \subseteq \mathcal{R}_{\text{with-TS}}\).

Initialize \(\tau_1 = \tau\) and \(x_{n,1} = x_n^*, \forall n \in \mathcal{N}\), where \((x_1^*, \ldots, x_N^*)\) denotes the optimal solution to (P1) for the case without time sharing. Moreover, initialize \(\tau_q = 0\) and \(x_{n,q} = (r_n r_{nx} + w^2 h_n^2)/r_{nx}, \forall n \in \mathcal{N}, \forall q \neq 1\). At each iteration \(itr, itr = 1, 2, \ldots\), we design \(\tau_q\)’s and \(x_{n,q}\)’s alternatively according to the following procedure. First, we solve (P4) over \(\tau_q, \forall q \in \mathbb{Q},\) while the rest of variables are all fixed. The resulting problem is a linear programming (LP) which can be efficiently solved using the existing software, e.g., CVX [24]. We update \(\tau_q, \forall q \in \mathbb{Q},\) as the obtained solution. Next, we optimize the load resistance for different configurations sequentially, e.g., starting from configuration 1 to \(Q\). For each configuration \(q\), we solve (P4) over \(x_{n,q}, \forall n \in \mathcal{N},\) with the rest of variables all being fixed. We thus consider the following optimization problem.

\[
(P4 - q) : \min_{\{\mathbf{x}_{n,q}\} \in \mathcal{N}} \sum_{n \in \mathcal{N}} \frac{|v_{nx}|^2}{2\tau} r_{nx} + w^2 \sum_{k \in \mathbb{N}_q} h_k^2 (r_k + x_{k,q})^{-1} \tau_q
\]  
\[
\text{s.t. } \sum_{n \in \mathcal{N}} \frac{|v_{nx}|^2}{2\tau} w^2 h_n^2 x_{n,q} (r_n + x_{n,q})^{-2} \tau_q \geq p_{n,-q}, \forall n \in \mathcal{N}, \tag{26} \]

where \(p_{n,-q} = \sum_{m \in \mathbb{Q}_n \setminus \{q\}} |v_{mx}|^2 w^2 h_m^2 x_{m,n} (r_m + x_{m,n})^{-2} \tau_m / (2\tau (r_{nx} + w^2 \sum_{k \in \mathbb{N}_q} h_k^2 (r_k + x_{k,q})^{-1})^2)\). For each receiver \(n\), its load power constraint given in (25) is re-expressed in (28), where all power terms that do not involve \(x_{n,q}, \forall n \in \mathcal{N}\), are moved to the right-hand side (RHS) of the inequality, denoted by \(p_{n,-q}\), which is treated as constant in (P4−q). From (21), it follows that \(p_{n,-q}\) denotes the average power delivered to load \(n\) under all other configurations, \(m \in \mathbb{Q}_n \setminus \{q\}\). Problem (P4−q) has the same structure as (P1); as a result, we can solve it using an algorithm similar to Algorithm 1. We then update \(x_{n,q}, \forall n \in \mathcal{N},\) as the obtained solution to (P4−q), \(q = 1, \ldots, Q\).
TABLE V
ALGORITHM FOR (P4).

Algorithm 3

a) Initialize \( itr = 1, \Delta p > 0 \) and \( \Delta p_{\text{tx}} = p^{(0)}_{\text{tx}} = \infty \). Initialize \( \tau_1 = \tau \) and \( x_{n,1} = x^*_n, \forall n \in \mathcal{N} \). Initialize \( \tau_q = 0 \) and \( x_{n,q} = \left( r_n r_{\text{tx}} + w r^2 h^2_n \right) / r_{\text{tx}}, \forall n \in \mathcal{N}, \forall q \neq 1 \).

b) While \( \Delta p_{\text{tx}} > \Delta p \) do:
   - Solve (P4) over \( \tau_q, \forall q \in \mathcal{Q} \), assuming that the rest of variables are all fixed. Update \( \tau_q, \forall q \in \mathcal{Q} \), as the optimal solution to the resulting problem.
   - For \( q = 1 \) to \( q = Q \) do:
     - Solve (P4\( -q \)) using similar algorithm as Algorithm 1. Update \( x_{n,q} \), \( \forall n \in \mathcal{N} \), as the solution to (P4\( -q \)).
   - Compute (24) and save the obtained value as \( p^{(itr)}_{\text{tx}} \). Accordingly, set \( \Delta p_{\text{tx}} = p^{(itr-1)}_{\text{tx}} - p^{(itr)}_{\text{tx}} \).
   - Set \( itr = itr + 1 \).

d) Return \( x_{n,q}'s \) and \( \tau_q's \) as the solution to (P4).

Fig. 8. Power regions without versus with time sharing.

At the end of each iteration \( itr \), we compute \( p^{(itr)}_{\text{tx}} \) as the objective value given in (24). The algorithm stops when \( \Delta p_{\text{tx}} = p^{(itr-1)}_{\text{tx}} - p^{(itr)}_{\text{tx}} \leq \Delta p \) holds, with \( p^{(0)}_{\text{tx}} = \infty \) by default and \( \Delta p > 0 \) denoting a given stopping threshold.

The above alternating optimization based algorithm for (P4) is summarized in Table V as Algorithm 3. Note that the convergence of Algorithm 3 for (P4) is ensured since the objective value of (P4), i.e., \( p^{(itr)}_{\text{tx}} \), is non-increasing over iterations, while the constraints in (25) and (26) are all satisfied at each iteration.

D. Numerical Example

We consider the same system setup as that in Section III-B. We set \( x_n = 1\Omega \) and \( \pi_n = 100\Omega, \forall n \in \mathcal{N} \). For Algorithm 3 in the case with time sharing, we set \( \Delta p = 10^{-3} \).

Figs. 8(a), 8(b), and 8(c) show power regions \( \mathcal{R}_{\text{without-TS}} \) versus \( \mathcal{R}_{\text{with-TS}} \) given by (22) and (23), respectively, under three different resonant angular frequencies of \( w = 14.2 \times 10^6 \text{rad/sec}, w = 42.6 \times 10^6 \text{rad/sec}, \) and \( w = 127.8 \times 10^6 \text{rad/sec} \), respectively. For the purpose of exposition, we consider only the two-user case for Fig. 8 by assuming receiver 3 is disconnected from its load, i.e., \( s_3 = 0 \). It is observed that \( \mathcal{R}_{\text{with-TS}} \) is always larger than
Algorithm 1 and Algorithm 3, as expected. It is also observed that the power region difference becomes less significant as the operating frequency decreases. This result is explained as follows. When $w$ is sufficiently small, the power delivered to each load $n$ in the case without time sharing, given in (8), can be approximated as $p_n \approx |v_{tx}|^2 w^2 h_n^2 x_n (r_n + x_n)^{-2}/(2r_{tx}^2)$, from which it follows that there is no evident coupling effect among receivers. In this regime, given load resistance $x_n$, the power received by load $n$ does not depend on whether the other receivers are connected to their loads or not. As a result, time sharing is less effective and hence cannot enlarge the power region over that without time sharing.

Next, we consider again the case of three users in the system. We fix $w = 42.6 \times 10^6$ rad/sec and $p_1 = p_2 = 5$ W. Fig. 9 compares the transmitter power $p_{tx}$ obtained using Algorithms 1 and 3 over $p_3$, with $0 < p_3 \leq 55.9$ W. It is observed that Algorithm 3 achieves lower $p_{tx}$ than Algorithm 1 over all values of $p_3$. This is expected since time sharing provides extra degree of freedom for multiuser power transmission scheduling. Consequently, the time allocation and load resistance for the receivers can be jointly optimized to further reduce the transmitter power as compared to the case without time sharing where only load resistance is optimized.

VI. CONCLUSION

In this paper, we study a point-to-multipoint WPT system via MRC. We derive closed-form expressions for the input and output power in terms of the system parameters for arbitrary number of receivers. Similar to other multiuser wireless applications such as those in wireless communication and far-field microwave based WPT, a near-far fairness issue is revealed in our considered MRC-WPT system. To tackle this problem, we propose a centralized charging control algorithm for jointly optimizing the receivers’ load resistance to minimize the transmitter power subject to the given load power constraints. For ease of practical implementation, we also propose a distributed
algorithm for receivers to iteratively adjust their load resistance based on local information and one-bit feedback from each of the other receivers. We show by simulation that the distributed algorithm performs very close to the centralized algorithm with a finite number of iterations. Last, we characterize the achievable multiuser power regions for the loads without and with time sharing and compare them through numerical examples. It is shown that time sharing can help further mitigate the near-far issue by enlarging the achievable power region as compared to the case without time sharing. As a concluding remark, we would like to point out that MRC-WPT is a promising new research area in which many tools from signal processing and optimization can be applied to devise innovative solutions, and we hope that this paper will open up an avenue for more future works along this direction.

APPENDIX

A. Proof of Proposition 3.1

From (7), it follows that
\[
\frac{\partial p_{tx}}{\partial x_n} = \frac{|v_{tx}|^2}{2} \frac{w^2 h_n^2 (r_n + x_n)^{-2}}{\left( r_{tx} + w^2 \sum_{k=1}^{N} h_k^2 (r_k + x_k)^{-1} \right)^2},
\] (29)
where it can be easily verified that \( \frac{\partial p_{tx}}{\partial x_n} > 0 \) over \( x_n > 0 \). This means that \( p_{tx} \) strictly increases over \( x_n > 0 \). The proof of Proposition 3.1 is thus completed.

B. Proof of Proposition 3.2

From (8), it follows that for \( m \neq n \),
\[
\frac{\partial p_m}{\partial x_n} = \frac{|v_{tx}|^2}{2} \frac{2 w^4 x_m h_m^2 h_n^2 (r_m + x_m)^{-2}}{\left( r_{tx} + w^2 \sum_{k=1}^{N} h_k^2 (r_k + x_k)^{-1} \right)^3},
\] (30)
where it can be easily verified that \( \frac{\partial p_m}{\partial x_n} > 0 \) over \( x_n > 0 \). This means that \( p_m, m \neq n, \) strictly increases over \( x_n > 0 \). Similarly, for \( m = n \), from (8), it follows that
\[
\frac{\partial p_n}{\partial x_n} = \frac{|v_{tx}|^2}{2} \frac{w^2 h_n^2 (r_n + x_n)^{-3}}{\left( r_{tx} + w^2 \sum_{k=1}^{N} h_k^2 (r_k + x_k)^{-1} \right)^3} \left( (r_{tx} + \phi_n) (r_n - x_n) + w^2 h_n^2 \right),
\] (31)
where \( \phi_n = w^2 \sum_{k \in \mathcal{N} \setminus \{n\}} h_k^2 (r_k + x_k)^{-1} \). It can be easily verified that \( \frac{\partial p_n}{\partial x_n} > 0 \) over \( 0 < x_n < \hat{x}_n \), with \( \hat{x}_n > 0 \) given in (11), and \( \frac{\partial p_n}{\partial x_n} < 0 \) over \( x_n > \hat{x}_n \). The proof of Proposition 3.2 is thus completed.

C. Proof of Proposition 3.3

Since \( \frac{\partial p_{sum}}{\partial x_n} = \sum_{k=1}^{N} \frac{\partial p_k}{\partial x_n} \), we can easily prove Proposition 3.3 using the same argument for the proof of Proposition 3.2. The detail is thus omitted for brevity.
D. Proof of Proposition 3.4

From (9), it follows that
\[
\frac{\partial \rho}{\partial x_n} = \frac{|v_{ix1}|^2 w^2 h_n^2 (r_n + x_n)^{-4} \left( x_n^2 (\varphi_n - \phi_n - r_{ix}) + 2r_n \varphi_n x_n + r_n w^2 h_n^2 + r_n^2 (\varphi_n + \phi_n + r_{ix}) \right)}{(r_{ix} + w^2 \sum_{k=1}^{N} k^2 (r_k + x_k)^{-1})^2}. \tag{32}
\]
Accordingly, it can be verified that when \( \varphi_n - \phi_n - r_{ix} \geq 0 \), \( \rho \) strictly increases over \( x_n > 0 \). Otherwise, if \( \varphi_n - \phi_n - r_{ix} < 0 \), then \( \rho \) increases over \( 0 < x_n < \bar{x}_n \) due to the fact that \( x_n^2 (\varphi_n - \phi_n - r_{ix}) + 2r_n \varphi_n x_n + r_n w^2 h_n^2 + r_n^2 (\varphi_n + \phi_n + r_{ix}) < 0 \) and the rest of terms in the right-hand side of (32) are all positive; similarly \( \rho \) declines over \( x_n > \bar{x}_n \). The proof of Proposition 3.4 is thus completed.

E. Impedance Characterization of EM Coils

As shown in Fig. 10, we consider two circular EM coils, indexed by \( i, i \in \{1, 2\} \), in the free space (no external electric and/or magnetic fields exist). Without loss of generality, we assume that the center of EM coil 1 is located at the origin, i.e., \( (x = 0, y = 0, z = 0) \), and its surface normal vector is given by \( \vec{n}_1 = \vec{z} \). On the other hand, we assume that the center of EM coil 2 is located at \( (x = x', y = y', z = z') \) and its surface normal vector is given by \( \vec{n}_2 = n_{x,2} \vec{x} + n_{y,2} \vec{y} + n_{z,2} \vec{z} \), with \( \sqrt{n_{x,2}^2 + n_{y,2}^2 + n_{z,2}^2} = 1 \), and \( n_{x,2} : n_{y,2} : n_{z,2} = x' : y' : z' \). As shown in Fig. 11 we assume that each EM coil \( i \) consists of \( b_i \) closely wound turns of round shaped wire, where the inner radius of coil is denoted by \( e_{\text{inner},i} > 0 \), while the outer radius is denoted by \( e_{\text{outer},i} > e_{\text{inner},i} \).

Accordingly, the average radius of each EM coil \( i \) and the radius of the wire used to build this coil are obtained as \( e_{\text{ave},i} = (e_{\text{outer},i} + e_{\text{inner},i})/2 \) and \( e_{\text{wire},i} = (e_{\text{outer},i} - e_{\text{inner},i})/2 \), respectively. Let \( r_i \) and \( l_i \) denote the resistance and self-inductance of each EM coil \( i \). Given \( e_{\text{wire},i} \ll e_{\text{ave},i} \), i.e., the wire is much thinner that the average radius,
which is practically valid, we have [7]:

\[
\begin{align*}
    r_i &= \frac{2\sigma_i b_i e_{ave,i}}{2 e_{wire,i}}, \\
    l_i &= b_i^2 e_{ave,i} \mu \left( \ln \left( \frac{8 e_{ave,i}}{e_{wire,i}} \right) - 2 \right),
\end{align*}
\]

where \( \sigma_i \) is the resistivity of the wire used in EM coil \( i \) and \( \mu = 4\pi \times 10^{-7} \text{N/A}^2 \), which denotes the magnetic permeability of the air. Let \( h \) denote the mutual inductance between the two EM coils. By assuming \( d \triangleq \sqrt{x'^2 + y'^2 + z'^2} \gg e_{ave,1}, e_{ave,2} \), i.e., the distance between the two EM coils is much larger than their average radiuses, we have [21]:

\[
\begin{align*}
    h &= \frac{\pi \mu b_1 b_2 e_{ave,1}^2 e_{ave,2}^2}{4d^3} \left( 3 \cos(\theta') \sin(\theta') \cos(\phi') n_x,2 \\
    &\quad + 3 \cos(\theta') \sin(\theta') \sin(\phi') n_y,2 + (2 \cos^2(\theta') - \sin^2(\theta')) n_z,2 \right),
\end{align*}
\]

where \( \theta' = \cos^{-1}(z'/d) \) and \( \phi' = \tan^{-1}(y'/x') \).
