Thus, research has been pursued for minimal blood loss with use of various hemostatic agents, such as fibrin and tranexamic acid. Floseal (Baxter, Deerfield, IL, USA), a thrombin-based hemostatic agent, is composed of two independent hemostasis-promoting agents, bovine-derived gelatin matrix component and human-derived thrombin. A high concentration of human thrombin accelerates blood clotting by converting fibrogen to fibrin, and gelatin matrix swells upon contact with moisture, producing a tamponade effect to control blood loss. It has been employed in a wide range of medical fields including orthopedic surgery, neurosurgery, otolaryngology, and obstetrics and gynecology; thus, it is expected to be useful in TKA that involves substantial blood loss.

In this study, we investigated the impact of intraarticular injection of the thrombin-based hemostatic agent on blood loss following TKA.

**Materials and Methods**

This study was conducted under Institutional Review Board.
A total of 100 patients who underwent unilateral TKA under the diagnosis of degenerative osteoarthritis at our institution between December 2011 and June 2013 were included in this study. The patients were randomly assigned to either the experimental group with use of the thrombin-based hemostatic agent (group I, n=50) or the control group without the agent (group II, n=50) (Table 1). The implants of choice were either PFC Sigma (DePuy Orthopaedics Inc., Warsaw, IN, USA) or Scorpio NRG (Stryker, Allendale, NJ, USA). Ten patients in each group had been on anticoagulant therapy due to cardiovascular diseases or cerebrovascular diseases, which was discontinued at least 5 days prior to surgery and was re-instituted on the 5th postoperative day if there was no sign of blood loss. Patients who could not tolerate discontinuation of the anticoagulant therapy, underwent bilateral TKA, or had bleeding disorders were excluded from the study.

With the patient placed in the supine position, the surgery was performed through a midline incision. A tourniquet was applied prior to skin incision at 350 mmHg and released upon completion of skin closure. Femoral resection was done using an intramedullary alignment guide and tibial resection was carried out using an extramedullary alignment guide. Bone cement was used for fixation in the femur and tibia. The patella was resurfaced in 2 knees in group I and in 5 knees in group II after intraoperative confirmation of advanced arthritis in the patellofemoral joint. In group I, after femoral and tibial component placement, 5 mL thrombin-based hemostatic agent was applied to the medial, lateral, and posterior compartments and the suprapatellar bursa before liner insertion (Fig. 1). A drainage tube was placed in all patients and drainage was started 1 hour after surgery. In all patients, quadriceps femoris strengthening exercises and active joint exercises were initiated from the 1st postoperative day. Ambulation was encouraged when quadriceps femoris strengthening exercises could be accomplished without difficulty.

Hemoglobin level was measured daily from the preoperative day to the 3rd postoperative day. The drain output was measured on the day of surgery and 1st postoperative day, and the tube was removed on the 2nd postoperative day. The total red blood cell loss within 24 postoperative hours was calculated using preoperative circulating blood volume and postoperative hematocrit change taking into account that hemodynamic changes are caused by intraoperative/postoperative blood loss. The following equation suggested by Gross\textsuperscript{12} in 1983 was used for the calculation of total red blood cell loss: total red blood cell loss=preoperative circulating blood volume×\((\text{preoperative hematocrit}−\text{postoperative hematocrit})/\text{mean hematocrit}\)\textsuperscript{13}.

The preoperative circulating blood volume was calculated using the method of Nadler et al.\textsuperscript{14} as follows: preoperative circulating blood volume=\(k_1\times\text{height (m)}+k_2\times\text{weight (kg)}+k_3\) (K is a constant, \(k_1=0.3669, k_2=0.03219, k_3=0.6041\) for male and 0.3561, 0.03308, 0.1833 for female, respectively).

Packed red blood cell transfusion was performed if a hemoglobin level was below 8.5 g/dL for 3 postoperative days. The pre-transfusion hemoglobin values were included in the statistical analysis, but post-transfusion levels were excluded. The intraoperative blood loss was not included in the statistical analysis due to the difficulty of objective measurement caused by the tourniquet use. At 1 week after surgery, vascular sonography was performed to identify the presence of deep venous thrombosis, and the surgical site was examined to assess the occurrence of wound infection or bleeding.

Statistical analysis was done using SPSS ver. 18.0 (SPSS Inc., Chicago, IL, USA). Patient characteristics, such as gender and surgical site, were compared using chi-square test. Pre- and postoperative changes were compared using t-test. The level of

### Table 1. Demographic Data

| Variable         | Group I     | Group II    | p-value |
|------------------|-------------|-------------|---------|
| No. of patients  | 50          | 50          |         |
| Age (yr)         | 68.8±7.70   | 69.0±6.66   | 0.895   |
| Sex (male:female)| 4:46        | 8:42        | 0.211   |
| Body mass index (kg/m\(^2\)) | 26.41±4.30 | 24.81±3.07 | 0.063   |
| CR:PS type       | 22:28       | 26:24       |         |

Values are presented as mean±standard deviation or number.
CR: cruciate retraining, PS: posterior cruciate substituting.
significance for all tests was set at p<0.05.

Results

1. Patient Characteristics
In group I, there were 4 males and 46 females, and their mean age was 68.8 years. In group II, there were 8 males and 42 females, and their mean age was 69.0 years. There was no statistically significant intergroup difference with regard to the age, gender, implant type, and body mass index (p>0.05).

2. Postoperative Blood Loss (Drain Output)
The mean postoperative drain output was 525 mL (393 mL on the day of surgery+132 mL on the 1st postoperative day) in group I and 667 mL (513 mL on the day of surgery+154 mL on the 1st postoperative day) in group II. Thus, the postoperative blood loss volume was 22% less in group I than group II, showing statistical significance (p=0.01) (Table 2).

3. Hemoglobin Level Change
Pre-transfusion hemoglobin levels were included in statistical analysis and the post-transfusion levels were not analyzed. In group I, the mean change in hemoglobin level between the preoperative period and the 3rd postoperative day was 2.88 g/dL: the value was 12.13 g/dL preoperatively, 10.18 g/dL on the 1st postoperative day, 9.45 g/dL on the 2nd postoperative day, and 9.25 g/dL on the third postoperative day. In group II, the mean hemoglobin level change was 3.00 g/dL during the same period: the value was 12.00 g/dL preoperatively, 9.95 g/dL on the 1st postoperative day, 9.17 g/dL on the 2nd postoperative day, and 9.00 g/dL on the 3rd postoperative day. Although 0.12 g/dL less change was noted in group I, the difference was not statistically significant between the groups (p>0.05) (Table 3).

4. Allogeneic Blood Transfusion
In group I, allogeneic blood transfusion was performed in a total of 18 patients (5 on the 1st postoperative day, 10 on the 2nd postoperative day, 3 and on the 3rd postoperative day). The blood transfusion rate was significantly different between the groups (p=0.043) (Table 4).

5. Total Red Blood Cell Loss within 24 Hours after Surgery
The total red blood cell loss within the first 24 hours after surgery was measured as an average of 593 mL (range, 13 to 1,478 mL) in group I and 609 mL (range, 101 to 1,494 mL) in group II. The 16 mL of difference between the groups did not reach statistical significance (p=0.655).

Discussion

Allogeneic blood transfusion is often necessary in surgery that involves substantial blood loss. Unfortunately, it has been associated with some adverse outcomes: disease transmission, such as AIDS and hepatitis, alloantibody responses, and graft-versus-host reactions\(^3\). Thus, efforts have been made to reduce intraopera-

tive blood loss using hypotensive anesthesia and administration of hemostatic agents\textsuperscript{1,3-5,15}, and the latter has been the focus of recent research.

Considering that hemodynamic changes after TKA result from coagulation and fibrinolysis, studies have suggested that intravenous administration of dextran, tranexamic acid, amnoca proic acid, and aprotinin would be effective in reducing perioperative blood loss\textsuperscript{15-19}.

Besides intravenous injection, direct application of hemostatic agents on the operative site has been addressed in many studies. Marmor et al.\textsuperscript{10} coated the operative site with fibrinogen concentrate to induce fibrin clot formation, which resulted in 16\% reduction in the total blood loss and 76\% reduction in the intraoperative blood loss. In the study, they suggested that fibrinogen concentrates would be more beneficial for reducing inapparent blood loss than postoperative blood loss. Song and Park\textsuperscript{20} compared the hemoglobin level, hematocrit value, and the frequency of autotransfusion between 40 TKA patients with fibrin glue that contains fibrinogen and 31 TKA patients without fibrin glue and reported that fibrin glue was remarkably effective for bleeding control.

In our study, we used Floseal, a hemostatic agent composed of bovine collagen granules and human thrombin, which has an increased presence in orthopedic surgery, neurosurgery, thoracic surgery, and obstetrics and gynecology. Kim et al.\textsuperscript{21} investigated the efficacy of the thrombin-based hemostatic matrix after unilateral TKA. The 24-hour drain output was not significantly different between the Floseal group (n=97) and the control group (n=97; 711 mL vs. 701 mL). The knee range of motion and visual analog scale score were not significantly different between the groups. However, a statistically significant intergroup difference was noted in the hemoglobin level change: notably less changes were observed between the preoperative values and the first and second postoperative day values in the Floseal group\textsuperscript{21}. In our study, the total drain output and transfusion rates were significantly low in the Floseal group, whereas the hemoglobin level change and 24-hour red blood cell loss showed no significant difference between the groups. Kim et al.\textsuperscript{20} reported that there was a significant relation between tourniquet pressure and subcutaneous bleeding after TKA: the amount of subcutaneous bleeding after TKA significantly increased when the surgery was performed under a tourniquet pressure of 320 mmHg than 250 mmHg. In our study, TKA was performed under a relatively high tourniquet pressure of 350 mmHg, thus we could have underestimated insensible blood loss caused by tourniquet application. In addition, blood transfusion was performed in patients with <8.5 g/dL hemoglobin level without taking consideration into symptoms, blood pressure, and heart rate. Other limitations of this study include that 1) the hemoglobin level changes were relatively insignificant by excluding from the analysis the values obtained from the 4th postoperative day and after transfusion, 2) and the potential risk of complications, such as infection, could not be assessed due to the lack of long-term follow-up.

Conclusions

The use of a thrombin-based hemostatic agent resulted in 22\% decrease in drain output and significant reduction in the need for blood transfusion after TKA. The hemoglobin level change and 24-hour red blood cell loss were more notable in the hemostatic agent group (n=50) than in the control group (n=50), but the difference was not statistically significant. Therefore, we believe that thrombin-based hemostatic agents would be effective for reducing blood loss in orthopedic surgery, such as TKA that involves the risk of massive blood loss.
