One size fits all: equilibrating chemically different polymer liquids through universal long-wavelength description

Guojie Zhang,¹ Torsten Stuehn,¹ Kostas Ch. Daoulas,¹ and Kurt Kremer¹,‡
Max Planck Institute for Polymer Research, Ackermannweg 10, 55128 Mainz, Germany

Mesoscale behavior of polymers is frequently described by universal laws. This physical property motivates us to propose a new modeling concept, grouping polymers into classes with a common long-wavelength representation. In the same class samples of different materials can be generated from this representation, encoded in a single library system. We focus on homopolymer melts, grouped according to the invariant degree of polymerization. They are described with a bead-spring model, varying chain stiffness and density to mimic chemical diversity. In a renormalization group-like fashion library samples provide a universal blob-based description, hierarchically backmapped to create configurations of other class-members. Thus large systems with experimentally-relevant invariant degree of polymerizations (so far accessible only on very coarse-grained level) can be microscopically described. Equilibration is verified comparing conformations and melt structure with smaller scale conventional simulations.

Predicting properties of polymeric materials with computer simulations often requires their description with microscopic detail. This is, however, challenging due to slow dynamics of entangled “spaghetti-like” polymers and the need to address systems with dimensions significantly larger than the coil size (to avoid finite-size effects). To circumvent these difficulties, hierarchical strategies gradually equilibrating the material on different observation scales are attractive (see ref.² and references therein). First the crudest level is addressed with models, representing a large amount of microscopic degrees of freedom by a single effective particle. Details on shorter wavelengths are then gradually reinserted until all chemical details are recovered. Computations remain tractable since backmapping requires only local sampling.

Implicitly hierarchical approaches assume that the long-wavelength structure is correctly described by the crude model and is insensitive to chemical details. Scale-decoding in polymers can be rigorously justified and linked to universality of the long-wavelength behavior, often described by generic laws adsorbing chemistry-specific details into few parameters. Since different polymers can be mapped to the same point of parameter space, classes of systems with identical long-wavelength properties can be defined. This allows simplifying significantly the hierarchical modeling of polymeric materials by creating “material-genomic” libraries of morphologies with the correct long-wavelength behavior of different classes. For an entire class such morphology must be generated only once, preferably using the most simple microscopic representation. This system can be even a chemistry non-specific model (e.g., bead-spring) which nevertheless maps on the same point of parameter space. Atomistic representations of any class-member can be recovered reinserting chemical details into the common long-wavelength description with standard techniques.

Here the implementation of this concept is demonstrated for amorphous homopolymer melts. Despite their simplicity, they present significant interest for basic polymer physics (e.g., as a framework for studying rheology) and industry. Polymer melts are systems where long strongly interdigitating molecules fill space in a random walk fashion. The number of molecules crossing the volume of a test chain in a melt of type γ is proportional to \( N^{1/2}_{(\gamma)} = \rho_{(\gamma)} R_{(\gamma)}/N_{(\gamma)} \), where \( \rho_{(\gamma)} \), \( R_{(\gamma)} \), and \( N_{(\gamma)} \) are the monomer density, root mean-square end-to-end distance, and polymerization degree respectively. The invariant degree of polymerization, \( N_{(\gamma)} \), presents a natural choice for arranging homopolymer melts into groups with common static long-wavelength properties. Indeed mesoscale conformations and liquid structures are known to be universal functions of this quantity (see below). Generally for dynamical properties non-universalities can appear even in the long-wavelength limit, however there is evidence that the invariant degree of polymerization of subchains between two consecutive entanglements is similar for all polymers. \( N_{(\gamma)} \) plays a key role in more complex systems, e.g. it controls in a universal way thermodynamic properties in symmetric block-copolymers.

Let us consider different melts (indexed by α), having the same \( N_{(\gamma)} \) as the \( l \)-th library melt (see Fig. 1). For each melt the regime of universal long-wavelength behavior can be defined introducing a coarse-graining length scale, \( \Delta L_{(\gamma)} = R_{(\gamma)}/l \), in spirit of renormalization group theories. In principle the observation scale separating chemistry-specific and universal behavior cannot be exactly defined, thus \( \Delta L_{(\gamma)} \) presents at this stage an arbitrary “large” scale. Introducing \( \Delta L_{(\gamma)} \) renormalizes the microscopic coordinate space as \( \tilde{r} = r/\Delta L_{(\gamma)} \). The shortest subchains that are resolved during coarse-graining contain a number of monomers, \( N_{b(\gamma)} \), such that their root mean-square end-to-end distance, \( R_{b(\gamma)} \), equals \( \Delta L_{(\gamma)} \cdot \Delta L_{(\gamma)} \). \( N_{b(\gamma)} \) can be simply related to \( N_{(\gamma)} \) within the Flory hypothesis (FH). Linking monomers into long chains in combination with incompressibility reduces in-

---

termolecular monomer-monomer contacts on the scale of chain-size creating a “correlation hole”. FH proposes that intramolecular interactions tending to swell a chain are canceled by interactions with the other molecules, forming the “soft walls” of the correlation hole. Hence the polymer conformations on the mesoscale are ideal random walks, so that \( R_{\beta(\gamma)}^2 = N_{b(\gamma)} b_{e(\gamma)}^2 \). Thus \( N_{b(\gamma)} = \Delta L^2_{\gamma}/b_{e(\gamma)}^2 \). The chemistry-specific coefficient, \( b_{e(\gamma)}^2 \), is the squared effective bond length in the normalized space.

All melts are represented in the renormalized space by ensembles of chains of spheres (blobs) with the same average diameter \( R_{b(\gamma)} = 1 \). Combining known theoretical results, we argue that under certain conditions such an ensemble constitutes a common long wavelength description for melts at given \( N_{(\alpha)} \). In practice, stored (library) configurations will have a fixed number of chains, \( n_{(\alpha)} \), and volume, \( V_{(\alpha)} \). Hence to identify these conditions it is natural to consider the canonical ensemble. The \( \alpha \)-type and the library melt will have the same conformations and structure in the renormalized space when (a) they are represented by the same amount of blobs, (b) contain an equal number of chains, \( n \), and (c) have the same rescaled volume, \( \tilde{V} = V_{(\gamma)}/\Delta L^3_{\gamma} \) (in fact, since \( N_{(\gamma)} \) is the same, the last condition follows from the other two).

When ideal random walks are coarse-grained into a blob representation, the statistics: (a) of the distance, \( \bar{l} \), between the center-of-mass (COM) of two sequential blobs and (b) of the angle, \( \theta \), between two vectors joining the COM of a blob with the COMs of the preceding and the succeeding blob, are universal in renormalized space. Since the distributions of internal coordinates \( \bar{l} \) and \( \theta \) are universal, the conformations of coarse-grained chains in the library and \( \alpha \)-type melts with an identical amount of blobs will be the same. The average mean-square distance of two blobs with ranking numbers \( s_1 \) and \( s_2 \) along the chain contour is a representative quantifier of these conformations, given by:

\[
\tilde{R}_{CG}^2(s) = s(l^2) \left[ \frac{1 + p}{1 - p} - \frac{2p(1 - p^s)}{s(1 - p^2)} \right]
\]

\( (l^2) = \frac{2}{3}, p = (\cos(\pi - \theta)) \approx 0.22, \) and \( s = |s_2 - s_1| \).

FH was corrected, demonstrating that the volume spanned by a chain presents a hierarchy of nested correlation holes of all possible subchains. This leads to weak self-avoidance and deviations from the ideal random walk behavior. The power-law dependence is replaced by:

\[
R_{CG}^2 = N_{CG} b_{CG}^2 \left[ 1 - c_1 N_{b(\gamma)}^{-1/2} + c_2 N_{CG}^{-1} \right]
\]

\( c_1 \) and \( c_2 \) are constants which, in general, are chemistry-specific (though for the end-to-end distance of long chains, the leading order correction in Eq. 2 reduces to a universal form).

Since the melts have the same number of chains it is straightforward to show that they have the same invariant degree of polymerization also on the level of subchains, where \( N_{b(\gamma)} = nN_{CG}/\tilde{V} \). Due to the same \( N_{b(\gamma)} \) the liquid structure on the scale of blobs will be the same. This conclusion can be traced back to de Gennes predictions that the average depth of the correlation hole for entire chains scales as \( \tilde{N}_{CG}^{-3/2} \). Modeling studies highlighted the universality of the shape of the correlation hole on intermediate scales. Blob-packing has been considered within integral equation theory predicting for their intermolecular pair distribution function:

\[
g_{CC}(\tilde{r}) = 1 - A_0 \tilde{N}_{b(\gamma)}^{-1/2} X_0(\tilde{r}, N_{CG})
\]

where \( A_0 = 6^{3/2}/2\pi^2 \) and \( X_0 \) is a universal function.

In summary, theoretical arguments suggest that configurations of homopolymer melts with the same invariant degree of polymerization can be obtained by backmapping a common blob-based representation. The latter is defined in spaces renormalized by the coarse-graining scale and originates from a library melt. In all practical applications, chain length is defined in terms of \( N_{(\alpha)} \) thus the matching library configuration is chosen.
such that, \( \Delta L_{(\gamma)}^{1/2} = \rho(\gamma) b^2_{(\gamma)} N_{(\gamma)}^{1/2} \). The coarse-graining scales of the modeled and library melts are arbitrary, provided that: (a) \( \Delta L_{(\gamma)} \) are sufficiently large for the sub-chains to be approximated by ideal random walks and (b) \( \Delta L_{(\alpha)} = (\rho(\alpha) b^2_{(\alpha)}/\rho(\gamma) b^2_{(\gamma)}) \Delta L_{(\alpha)} \). The last condition establishes the requirement that the number of the blobs be the same (equal to \( N_{CC} \)). Identifying \( N_{(\alpha)} \) and matching \( \Delta L_{(\gamma)} \) requires chemical-specific information, i.e. \( b^2_{(\gamma)} \).

Thus conventional microscopic simulations of small samples of melts with chain-lengths are performed. \( b^2_{(\gamma)} \) is calculated and fitted with the RHS of Eq. 2, to extract \( b^2_{(\gamma)} \), \( c_1 \), and \( c_2 \). These data provide also an estimate of \( \Delta L_{(\gamma)} \) at which the ideal random walk approximation is accurate. To perform the reference simulations several techniques are available, including configuration-assembly\(^{19,20} \) and rebridging Monte Carlo algorithms\(^{21} \).

Prior to fine-graining, the microscopic length scale is recovered back-transforming (cf. Fig. 1) the coordinate space of the blob-based description as \( r = \Delta L_{(\alpha)} \mathbf{r} \). In principle \( \Delta L_{(\alpha)} \) (equivalently \( N_{(\alpha)} \)) can be large, hampering direct reinsertion of microscopic details into the common blob-based representation. This difficulty can be circumvented\(^{22} \) through a hierarchical scheme where a low-resolution blob-based description undergoes a sequence of fine-graining steps. Each step increases resolution substituting every blob with a pair of smaller ones. On these intermediate scales conformations and liquid structure are affected substantially by microscopic features, so that the blob-based description becomes chemistry-specific. Nevertheless, fine-graining is feasible\(^{22} \) considering the blobs as soft spheres\(^{22} \) with simple interactions parameterized from the reference microscopic simulations. Alternatively, somewhat more complex chemistry-specific blob-based models can be developed from integral equation theories\(^{23,24} \), reducing in the future the need for such calibration data. Once the blobs become sufficiently small, microscopic details can be introduced. The general strategy\(^{22} \) is to reinsert the underlying subchains so that they comply, e.g. with the size and location of the COM of the blobs, and relax the reintroduced degrees of freedom.

As a proof-of-principle, we consider here homopolymer melts described with a generic microscopic model\(^{26} \).

Linear chains are represented with monomers linked by FENE springs augmented by an angular potential\(^{19} \)

\[ U(\theta) = \kappa(\gamma)(1 - \cos \theta_b) \]

where \( \theta_b \) is the angle between two sequential springs. Nonbonded interactions are captured through a Weeks-Chandler-Andersen (WCA) potential. For FENE and WCA interactions the standard parameterization\(^{22} \) is employed. We mimic chemical diversity by varying chain stiffness and/or monomer number density in the range \( 0 \leq \kappa(\gamma) \leq 1.5 \) and \( 0.60 \leq \rho(\gamma) \leq 0.85 \), respectively. All lengths and energies are expressed in units of \( \sigma \) (the characteristic WCA length) and thermal energy, \( k_B T \).

For the considered \( \kappa(\gamma) \) and \( \rho(\gamma) \), the required microscopic reference samples contained \( 400 - 700 \) chains with \( N_{(\gamma)} = 500 \), at most. These moderate sized systems were efficiently equilibrated through a configuration-assembly procedure\(^{19,20} \) implemented within the ESPResSo++ package\(^{27} \). From the reference configurations, \( b^2_{(\gamma)} \) is extracted as previously described (see Figure S1, Tables S1 and S2 in supplemental material\(^{28} \)) and plotted as a function of \( \kappa(\gamma) \) in the inset of Fig. 2. The main panel of Fig. 2 presents \( R^2_{(\gamma)}/N_b(\gamma) b^2_{(\gamma)} \) as a function of \( N_b(\gamma) \) for \( \kappa(\gamma) = 0 \) and 1.5. Fig. 2 demonstrates that for all considered \( \kappa(\gamma) \) the deviations from the ideal random walk limit drop below 2% roughly at the same threshold \( N_{th}^b(\gamma) = 100 \). For practical purposes, for such deviations we accept the ideal random walk statistics as a valid approximation. Thus \( \Delta L_{(\gamma)}^{th} = b_{(\gamma)}\sqrt{N_{th}^b(\gamma)} \) is taken as the smallest possible coarse-graining scale.

![Fig. 2. Main panel: Mean-square end-to-end distance of subchains, \( R^2_{(\gamma)} \), normalized by \( N_b(\gamma) b^2_{(\gamma)} \) as a function of \( N_b(\gamma) \) for \( \kappa(\gamma) = 0 \) and 1.5. Fig. 2 demonstrates that for all considered \( \kappa(\gamma) \) the deviations from the ideal random walk limit drop below 2% roughly at the same threshold \( N_{th}^b(\gamma) = 100 \). For practical purposes, for such deviations we accept the ideal random walk statistics as a valid approximation. Thus \( \Delta L_{(\gamma)}^{th} = b_{(\gamma)}\sqrt{N_{th}^b(\gamma)} \) is taken as the smallest possible coarse-graining scale.](https://example.com/f2.png)
for two melts with \( \tilde{N}(I) = 7.5 \times 10^3 \) and \( 15 \times 10^3 \) the internal distance plot \( R^2_{CG}(s)/s \). Within error bars the plots (solid and open circles) follow each other, reproducing closely the universal behavior of eq. 1 (dashed line). The magnitude of deviations is quantified in Figure S2. The blob-blob intermolecular pair distribution function is presented in Fig. 3b (solid and open circles) and is well described by the universal form in eq. 4.

Configurations of all other systems can be obtained by fine-graining the blob-based representation characterizing a library melt with the same \( \tilde{N}(I) \), on the scale \( \Delta L(I) = 16.5 \). As an example, we discuss two chemically different melts with \( \kappa\theta(\alpha) = 0.75, \rho(\alpha) = 0.60 \) (melt I) and \( \kappa\theta(\alpha) = 0, \rho(\alpha) = 0.85 \) (melt II). From the definition of invariant degree of polymerization and the data on \( b^2_{CG} \) from Fig. 3 it follows that both melts for \( \tilde{N}_{\text{melt I}} = 1500 \) and \( \tilde{N}_{\text{melt II}} = 2000 \) map on \( \tilde{N}(I) = 7.5 \times 10^3 \). For \( \tilde{N}_{\text{melt I}} = 3000 \) and \( \tilde{N}_{\text{melt II}} = 4000 \) both correspond to \( \tilde{N}(I) = 15 \times 10^3 \). Because of scale matching, the universal representation corresponds to \( \Delta L_{\text{melt I}} = 26.9 \) and \( \Delta L_{\text{melt II}} = 26.4 \), representing an underlying number of monomers \( N_{\text{melt I}} = 300 \) and \( N_{\text{melt II}} = 400 \), respectively. The universal description is hierarchically fine-grained22 (cf. Fig. 4) until reaching blob-based descriptions corresponding to \( N_{\text{melt I}} = 75 \) and \( N_{\text{melt II}} = 50 \). Microscopic details are introduced into these small blobs, employing constrained reinsertion of underlying subchains and gradual elimination of overlaps between monomers19,20.

To demonstrate equilibration of melts obtained from this procedure, Fig. 4 presents their internal distance plots, \( R^2(\alpha)(s)/s \), calculated on microscopic basis. \( s \) denotes the difference of the ranking numbers of monomers along chain contour and \( R^2(\alpha)(s) \) is their mean-square end-to-end distance. In all cases \( R^2(\alpha)(s)/s \) in the backmapped melts follow closely their counterparts in independent reference simulations (they deviate at most by 2%, see Figure S3). These observations strongly verify our approach, since internal distance plots are extremely sensitive to the quality of equilibration. Fig. 4 compares the total monomer-monomer pair distribution functions, \( g_{\text{CG}}(r) \), in the backmapped and reference melts, demonstrating that the local structure is correctly reproduced. It is instructive to convert the equilibrated melts I and II to blob-based representations in the renormalized space, corresponding to the initial coarse-graining scales \( \Delta L_{\text{melt I}} = 26.9 \) and \( \Delta L_{\text{melt II}} = 26.4 \). The calculated \( R^2_{CG}(s)/s \) and \( g_{CG}(r) \) are plotted in Fig. 4a, b and reproduce the universal behavior of the library melts.

These results confirm that a single melt can serve as a blueprint for configurations of different homopolymers described with microscopic resolution. Describing all systems through bead-spring models does not compromise the applicability of the approach to real materials. It has been already demonstrated that such models offer microscopic (albeit coarse-grained) description of real polymers when appropriately parameterized22,31. Moreover, the atomistic description can be recovered by backmapping the bead-spring representation through standard schemes29,31. So far, large samples with experimentally-relevant invariant degrees of polymerization, as those in the current work, have been generated only on drastically coarse-grained level32. Here these systems are described microscopically with minimum computational costs. For example, equilibrating a sample of melt II with \( \tilde{N}_{\text{melt II}} = 4000 \) at \( \tilde{N}(I) = 15 \times 10^3 \) (4 \times 10^6 monomers in total) required only six days on 32 processors (3.0 GHz). The concept was elaborated and verified for melts of linear chains but should be straightforward to extend to certain cases of non-linear molecules, e.g. branched or concatenated ring-polymers (named “Olympic gels”). In contrast, the implementation to nonconcatenated ring-polymers is challenging since coarse-graining into blobs relaxes microscopic non-crossability of subchains. It is important to explore whether similar strategies are applicable to materials with complex long-wavelength structure, depending on more control parameters23,34, e.g. microphase-separated block-copolymers.

It is a pleasure to thank Livia Moreira for fruitful dis-
cussions and Carlos Marques for carefully reading our manuscript. The computing time granted by the John von Neumann Institute for Computing (NIC) on the supercomputer JUROPA at Jülich Supercomputing Centre (JSC) is gratefully acknowledged.
