Subclinical depression

\section*{ABSTRACT}

Depressive symptoms, even at a subclinical level, have been associated with structural brain abnormalities. However, previous studies have used regions of interest or small sample sizes, limiting the ability to generalize the results. In this study, we examined neuroanatomical structures of both gray matter and white matter associated with depressive symptoms across the whole brain in a large sample. A total of 810 community-dwelling adult participants underwent measurement of depressive symptoms with the Center for Epidemiologic Studies Depression Scale (CES-D). The participants were not demented and had no neurological or psychiatric history. To examine the gray and white matter volume, we used structural MRI scans and voxel-based morphometry (VBM); to examine the white matter integrity, we used diffusion tensor imaging with tract-based spatial statistics (TBSS). In female participants, VBM revealed a negative correlation between bilateral anterior cingulate gray matter volume and the CES-D score. TBSS showed a CES-D-related decrease in fractional anisotropy and increase in radial and mean diffusivity in several white matter regions, including the right anterior cingulum. In male participants, there was no significant correlation between gray or white matter volume or white matter integrity and the CES-D score. Our results indicate that the reduction in gray matter volume and differences in white matter integrity in specific brain regions, including the anterior cingulate, are associated with depressive symptoms in women.

1. Introduction

Major depressive disorder is associated with decreased brain volume or changes in white matter integrity, particularly in frontal areas (Abe et al., 2010; Bremer et al., 2002; Egger et al., 2008; Kiseppä et al., 2010; Shimony et al., 2009) and in medial temporal areas such as the hippocampus (Abe et al., 2010; Campbell et al., 2004; Videbech and Ravnik, 2004). Recently, depressive symptoms that do not meet the criteria for major depression have received increased attention. Understanding this preclinical state precisely is important for preventing major depressive disorder (Cuijpers et al., 2004). Several previous reports have suggested that depressive symptoms at a subclinical level have some of the same neural correlates as those in major depression (Hayakawa et al., 2013; Lavretsky and Kumar, 2002; Lyness et al., 1999). However, most previous studies on this issue have been based on regions of interest or small sample sizes, limiting the ability to draw firm conclusions from them.

The purpose of this study was to investigate brain structures associated with depressive symptoms in gray and white matter across the whole brain in a large sample. We used voxel-based morphometry (VBM) and diffusion tensor imaging (DTI) with tract-based spatial statistics (TBSS). Both VBM and TBSS enable the global analysis of brain volume or white matter integrity without a priori identification of a region of interest. White matter integrity was represented by four DTI measures: fractional anisotropy (FA), mean diffusivity...
sequence in 50 axial sections (repetition time: 13,200 ms; echo time: 62 ms; field of view: 288 mm; slice thickness: 3 mm with no gap; acquisition matrix: 96 × 96; number of excitations: 1). Diffusion weighting was applied along 13 noncollinear directions with a b-value of 1000 s/mm², and a single volume was collected with no diffusion gradients applied (b = 0). The reconstructed voxel dimensions were 1.125 × 1.125 × 3.0 mm. Parallel imaging (array spatial sensitivity encoding technique) was used with an acceleration factor of 2.0.

2.3. Image processing

2.3.1. VBM analysis

All 3D SPGR images were processed and examined using the Statistical Parametric Mapping version 8 software (Wellcome Department of Imaging Neuroscience Group, London, UK; [http://www.fil.ion.ucl.ac.uk/spm]), where we applied VBM implemented in the VBM8 toolbox ([http://dbm.neuro.uni-jena.de/vbm.html]) with default parameters in MATLAB 7.7.0.471 (The MathWorks, Natick, MA, U.S.A.) running on a Windows computer. A ‘nonlinear only’ modulation was performed on all images during spatial normalization so that values in resultant images are expressed as volume corrected for brain size. The resultant modulated images were smoothed with a Gaussian kernel of 8 mm (full width at half maximum).

2.3.2. DTI analysis

We performed an unbiased whole-brain TBSS analysis ([http://www.fmrib.ox.ac.uk/fsi]) ([Smith et al., 2004]), which is part of FSL (FMRIB software library) 4.1 ([http://www.fmrib.ox.ac.uk/fsi]) ([Smith et al., 2004]). First, the raw diffusion data were corrected for eddy current distortion and head motion by using FDT (FMRIB’s Diffusion Toolbox) 2.0 ([Smith et al., 2004]) and corrected for spatial distortion due to gradient nonlinearity by using grad_unwarp ([Jovicich et al., 2006]). Following brain extraction by using BET2.1 ([Smith, 2002]), FA, MD, AD, and RD maps were created by fitting a tensor model to the diffusion data by using FDT. The FA data of all participants were then aligned into Montreal Neurological Institute (MN1) 152 space by using FNIRT 1.0 ([Smith et al., 2004]), which uses a b-spline representation of the registration warp field. The FMRIB58_FA standard-space image was used as the target. Next, a mean FA image was generated and thinned to create a mean FA skeleton, which represents the centers of all tracts common to the group. The mean FA skeleton image was thresholded at an FA value of 0.2 to prevent inclusion of non-skeleton voxels. The aligned FA data of each participant were then projected onto this skeleton. The MD, AD, and RD data were also aligned into MN1 152 space and projected onto the mean FA skeleton by using the FA data to find the projection vectors.

2.4. Statistical analysis

Relationships between four variables, CES-D, sex, age, and MMSE score, were tested by Pearson product moment correlation for all participants in the VBM analysis group and all participants in the TBSS analysis group.

2.4.1. VBM analysis

We performed voxel-wise correlation analyses by using the multiple regression function of SPM8 for all participants combined and for each sex separately. The CES-D score was treated as a covariate of interest. As nuisance variables, individual values for sex, age, and MMSE score were included for analysis of all participants combined, and age and MMSE for analysis of each sex. Two linear contrasts (1, −1) were made for positive and negative correlations, respectively. The significance level was set at family-wise error (FWE)-corrected P < 0.05.

MMSE: mini-mental state examination; CES-D: Center for Epidemiologic Studies Depression Scale. n.s.: not significant; P: two-sample t-test for men vs. women.

2.4.2. DTI analysis

Voxel-wise analyses of the skeletonized data were performed by using permutation-based, voxel-wise nonparametric testing as implemented in the randomize tool of FSL (Nichols et al., 2002). We identified areas in which FA, MD, AD, or RD was significantly correlated with the CES-D score. Sex and age were included as covariates for analysis of all participants combined, and age for analysis of each sex. Both positive and negative contrasts were tested with 5000 permutations. We used threshold-free cluster enhancement (Smith et al., 2009) as implemented within randomize, which provides the ability to perform cluster-based inferences without setting an arbitrary cluster-forming threshold. Voxel-wise statistical inference was made on the resulting statistical image, and the significance level was set at $P < 0.05$, corrected for the FWE rate.

3. Results

3.1. Participants

Of the 1148 volunteers who were screened, 338 met the exclusion criteria. Among the images from the resulting 810 participants, 18 3D SPGR images and 4 diffusion tensor images were excluded because of poor quality or artifacts. Images were therefore analyzed with VBM for 792 participants and with TBSS for 806 participants. There were no sex differences in age or MMSE in either group (Table 1). However, the CES-D score was significantly different between males and females in both analysis groups, and females were more depressed than males.

3.2. Relationships between CES-D and sex, age, and MMSE score

Table 2 shows Pearson product moment correlations between variables in each analysis group. The CES-D score was negatively correlated with sex and age. The sex is a dummy variable (female = 0, male = 1), so the negative correlation indicates that female participants tend to have higher CES-D scores. We found no correlation between CES-D and MMSE score. We found a negative correlation between the age and MMSE score.

3.3. VBM analysis of gray and white matter volume associated with CES-D

There was no significant correlation between gray matter volume and CES-D score for all participants combined. In the separate analysis of each sex, significant negative correlations between gray matter volume and the CES-D score were seen in the right rostral anterior cingulate gyrus and bilaterally in the dorsal anterior cingulate gyrus in female participants after adjusting for age and MMSE score (Table 3). Fig. 1 shows the extent of gray matter regions that had a volume reduction correlated with the CES-D score in female participants. There was no significant correlation between gray matter volume and the CES-D score in male participants. We observed no significant correlation between white matter volume and the CES-D score.

3.4. DTI analysis of white matter integrity associated with CES-D

In the analysis of all participants combined, there were no significant correlations between DTI measures and CES-D score. In the separate analysis of each sex, TBSS showed clusters of significant FA reduction, MD increase, and RD increase that correlated with the CES-D score in female participants (Fig. 2). 10.3% of all skeleton voxels showed significant negative associations between FA and CES-D, and 16.5% and 20.2% showed positive associations with RD and MD, respectively. The clusters of FA reduction included deep white matter in the bilateral frontal, temporal, and occipital lobes, external capsule, a large portion of the corpus callosum, right anterior cingulate, left fornix, and left uncinate. The clusters of RD increase were in almost the same structures as the clusters of FA reduction. The clusters of MD increase included deep white matter in the bilateral frontal, temporal, occipital, and parietal lobes, external capsule, superior longitudinal fasciculus, a large portion of the corpus callosum, right anterior limb of the internal capsule, left anterior cingulate, left fornix, and left uncinate. The cluster tool in FSL revealed that a largest cluster including the right dorsal anterior cingulum (Fig. 3) showed a significant reduction in FA (P-value at the peak voxel = 0.003, cluster size = 14,170) and an increase in RD (P-value at the peak voxel = 0.002, cluster size = 20,391) in association with the CES-D score. There were no significant clusters of increased FA, reduced MD, or reduced RD. AD showed no significant correlation with the CES-D score. There was no significant correlation between DTI measures and the CES-D score in male participants.
Table 3. Areas with significant gray matter volume reduction that correlated with depressive symptoms in female participants.

| Anatomical location                             | Talairach coordinates | P       | Cluster size |
|------------------------------------------------|------------------------|---------|--------------|
| Right rostral anterior cingulate gyrus         | 1 31 22                | 0.029   | 846          |
|                                                 | 15 32 21               |         |              |
|                                                 | 10 28 15               |         |              |
| Left dorsal anterior cingulate gyrus           | −1 4 34                | 0.037   | 785          |
| Right dorsal anterior cingulate gyrus          | 7 0 34                 |         |              |

Fig. 1. Results from multiple regression in female participants with a threshold of $P < 0.001$ (uncorrected data). Gray matter volumes in the right rostral anterior cingulate gyrus (a) and bilateral dorsal anterior cingulate gyrus (b) were negatively correlated with depressive symptoms ($P < 0.05$, FWE-corrected, cluster level). Cluster locations, sizes, and significance values are shown in Table 2. R and L indicate right and left, respectively. Color scale (0–4) represents $t$ values.

4. Discussion

To our knowledge, this is the first report to simultaneously study brain volume and white matter integrity associated with depressive symptoms in a large sample. We found statistically significant results only in the analysis of female participants and not in all participants combined or in male participants. The gray matter volume in the right rostral anterior cingulate and bilateral dorsal anterior cingulate gyrus decreased in association with increased depressive symptoms. There were white matter regions in which FA was negatively correlated with depressive symptoms. The CES-D score in most of the regions showed significant positive correlations with RD and MD.

4.1. The anterior cingulate gyrus and depressive symptoms

Volume reduction in the anterior cingulate gyrus has been reported in major depression (Botteron et al., 2002; Caetano et al., 2006; Lorenzetti et al., 2009). Several studies of community-dwelling populations revealed regional brain volume reductions in the anterior cingulate gyrus associated with depressive symptoms (Boes et al., 2008; Dotson et al., 2009). Boes et al. (2008) revealed volume reduction in the rostral anterior cingulate cortex of boys (but not girls) with subclinical depressive symptoms, suggesting that the rostral anterior cingulate cortex may act as a biological marker of vulnerability to, or as a trait marker of, depression. Moreover, some personality traits, such as harm avoidance, are known to be risk markers for major depression and have relationships with anterior cingulate volume (Gruca et al., 2003; Pujol et al., 2002). The present study, along with the previous reports, indicates that anterior cingulate volume reduction is associated with subclinical depressive symptoms. This is consistent with the hypothesis that this area is associated with vulnerability or future progression to major depression.

In addition, using TBSS, we discovered a negative correlation between FA and the CES-D score, and a positive correlation between RD and the CES-D score, in the right anterior cingulum in female participants. Increased RD reflects demyelination of axons in animal studies (Song et al., 2005). Although the anatomical underpinnings of RD in humans are not fully understood, when the TBSS results are combined with the VBM results, this study suggests that the volume reduction seen in the right anterior cingulate gyrus is the result of demyelination and/or abnormal myelination of the underlying white matter. In the left anterior cingulum, there was a positive correlation between MD and depressive symptoms. By definition, the difference between MD and RD depends on AD. In this study, although AD showed no significant correlation with depressive symptoms, the slight but non-significant variance of AD may have influenced the difference between RD and MD.

4.2. The white matter integrity and depressive symptoms

Disruption of integrity in some white matter regions has recently been reported in major depression (Abe et al., 2010; Kiepeppa et al., 2010; Shimony et al., 2009). Kiepeppa et al. (2010), using TBSS, suggested that FA is decreased in the left sagittal stratum, right cingulate gyrus, and posterior body of the corpus callosum in major depression. Fewer studies have focused on white matter integrity and subclinical depressive symptoms in healthy participants. As for individuals
Fig. 2. Correlation between FA, RD, MD, and the CES-D score as identified by TBSS in female participants. The statistical image was thresholded at $P<0.05$ and overlaid on the mean FA map of all participants. There were significant negative correlations between FA and the CES-D score (blue–light blue), and positive correlations between RD as well as MD and the CES-D score (red–yellow). L indicates left.
at risk for depression. Huang et al. (2011) reported lower FA values in white matter tracts including the left cingulum in healthy adolescents at familial risk of unipolar depression than in controls. Some personality traits identified as predisposing factors for affective disorders have been reported to associate with white matter microstructures in widespread brain areas (Aylng et al., 2012; Bjørnebekk et al., 2013; Westlye et al., 2011). Bjørnebekk et al. (2013) demonstrated that increased neuroticism is associated with decreased FA, as well as increased MD and RD in widespread regions of white matter. These regions include the long association fibers connecting the frontal, occipital, parietal, and temporal lobes; tracts connecting orbitofrontal regions with limbic regions; fiber tracts connecting thalamic nuclei with the frontal lobes; and cross-hemispheric pathways, including the corpus callosum. These white matter microstructures may underlie vulnerability to depression, and the present study suggests that widespread regions of white matter are also associated with depressive symptoms in community-dwelling women. The affected regions are broader than regions of volume reduction, suggesting that microstructural changes in white matter precede reductions in brain volume. Note that we did not control for preclinical anxiety as a potential confound in this study. Because anxiety and depression are highly correlated, the results of the current study could have been modulated by comorbid preclinical anxiety. A more detailed analysis of the potential effect of anxiety is an important direction for future research.

4.3. Sex difference

In this study, depressive symptoms were associated with brain volume and white matter integrity only in female participants. One possible explanation of this is that the sex difference per se influences the brain structure in major depression (Frodl et al., 2002; Hastings et al., 2004) and even in subclinical depression. Another explanation is the heterogeneity of the participant’s characteristics: the depressive symptoms measured by CES-D were statistically higher in women than in men. Therefore, the possibility remains that male participants who have the same depressive symptoms will show the same patterns in brain structure as females. Additional evidence from a more homogeneous group is needed to examine this possibility.

5. Conclusion

By using both VBM and TBSS in a large group of community-dwelling participants, we have shown associations between brain structures and depressive symptoms in female participants. Our findings show that frontal–limbic structures, including the bilateral anterior cingulate gyrus, are associated with depressive symptoms even at a subclinical level. Moreover, they show that white matter structure is associated with depressive symptoms in widespread regions.
