Nonequilibrium path-integral methods for computing quantum free-energy differences are applied to a quantum particle trapped in a harmonic well of uniformly changing strength with the purpose of establishing the convergence properties of the work distribution and free energy as the number of degrees of freedom $M$ in the regularized path integrals goes to infinity. The work distribution is found to converge when $M$ tends to infinity regardless of the switching speed, leading to finite results for the free-energy difference when the Jarzynski nonequilibrium work relation or the Crooks fluctuation relation are used. The nature of the convergence depends on the regularization method. For the Fourier method, the convergence of the free-energy difference and work distribution go as $1/M$, while both quantities converge as $1/M^2$ when the bead regularization procedure is used. The implications of these results to more general systems are discussed.

DOI: 10.1103/PhysRevE.78.041104

I. INTRODUCTION

In the preceding paper [1], a nonequilibrium path-integral method for computing free-energy differences based on combining the Jarzynski equality [2,3] and the Crooks fluctuation relation [4,5] with the path-integral formulation of the quantum mechanical partition sum [6–9] was presented. The path-integral representation of the canonical partition function is based on mapping a quantum system at finite temperature onto a classical system with additional degrees of freedom. A nonequilibrium process can be carried out on this isomorphic classical system along a well-defined trajectory in fictitious time. The Jarzynski and Crooks relations are valid for such a process, but only under the assumption that the work distribution converges as the parameter $M$ of the regularization procedure applied to the infinite dimensional path integral goes to infinity.

A regularization procedure is needed because particles are represented as objects with an infinite number of degrees of freedom in the path-integral formulation. As a result, nonequilibrium dynamical processes in this representation can lead to divergences in nonphysical quantities, such as the average total Hamiltonian of the particle or the work performed on the system in the fictitious process, which is a central quantity in the Jarzynski and Crooks relations. A regularization procedure restricts the number of degrees of freedom to a finite number $M$ and results in finite but $M$-dependent estimators for quantities of interest. In the regularized path-integral representation, one finds that the expression for the work takes the form of the difference between two quantities which diverge as $M \to \infty$. Having an estimator for physical quantities that take the form of the difference between two diverging quantities is not unusual in the context of path integrals [8], but this does make it important to establish the convergence properties of all relevant estimators. Furthermore, even when it can be demonstrated that the regularization procedure leads to convergent results, the viability of the nonequilibrium path-integral method as a means of computing quantum free-energy differences is strongly dependent on the rate of convergence of the regularized path integral to the exact quantum result. Neither the convergence nor the rate of convergence was addressed in detail in Ref. [1], although strong numerical evidence of convergence was presented for a quantum particle in a quartic potential.

In this paper, the rate of convergence of different regularization procedures is examined in detail for the special case of a quantum harmonic oscillator. Harmonic systems have the advantage of being often amenable to analytical treatment, allowing for closed form and exact solutions. Here, the convergence of the regularization procedure is studied in three regimes of the nonequilibrium process, i.e., the quasistatic, the finite time, and instantaneous switching. The work distribution is computed for each of these regimes and its convergence, as well as the convergence of free-energy difference are analyzed as the number of degrees of freedom goes to infinity. It will be shown that the free-energy difference and the work distribution converge for both the Fourier and the bead regularization procedures [1], with the latter converging more quickly.

The paper is organized as follows: Sec. II presents a brief overview of the method as it applies to the harmonic oscillator. Section III contains the analysis of the convergence of the free energy under different regularization schemes. The work distributions will be determined using a generating function technique explained in Sec. IV. In Secs. V–VII the quasistatic, finite time, and instantaneous switching processes, respectively, are studied. A comparison between the nonequilibrium work distribution generated by the fictitious dynamics and that generated with real time quantum dynamics is made in Sec. VIII. The conclusions are given in Sec. IX.

II. METHOD AND MODEL SYSTEM

We consider a one-dimensional quantum system with a Hamiltonian operator $\hat{H}(\lambda) = \hat{T} + \hat{V}$, with $\hat{T} = \hat{p}^{2}/(2m)$ and $\hat{V} = V(\xi, \lambda) = \frac{1}{2}m\dot{\lambda}^{2}$. Here the potential energy $V$ depends on a control parameter $\lambda$, which is equal to the square of the frequency $\omega$. The canonical partition function of this system at an inverse temperature $\beta$ is defined by

$$Z(\lambda) = e^{-\beta F(\lambda)} = \text{Tr} e^{-\beta \hat{H}(\lambda)},$$  

and can be written as [6,7]

$$Z(\lambda) = \int \mathcal{D}x e^{-(1/\beta)S[x,\lambda]},$$  

where the integral is over closed paths $x(s)$ [i.e., $x(0)$] and the Euclidean action $S$ is a functional of $x$ given by

$$S[x,\lambda] = \int_{0}^{\beta} ds \left[ \frac{1}{2} \frac{m}{\beta} \left( \frac{dx}{ds} \right)^{2} + \frac{1}{2} m \dot{\lambda}^{2} \right].$$  

Here and below the $s$ dependence of $x$ in integrals over $s$ will always be implied. For this one-dimensional harmonic system, the quantum free energy is known to be exactly

$$F(\lambda) = \beta^{-1} \ln[2 \sinh(\beta \omega/2)].$$  

The nonequilibrium path-integral approach of computing free-energy differences uses a nonequilibrium process defined by a fictitious dynamics in which $\lambda$ is changed from $\lambda_A = \omega_A^2$ to $\lambda_B = \omega_B^2$ over a time $\tau$, while starting at canonical equilibrium corresponding to $\lambda = \lambda_A$. This fictitious dynamics is derived by introducing a new field $p(s)$ which is also periodic in imaginary time, satisfying $p(s) = p(s + \beta \omega)$, leading to an expression that has the form of a classical partition function as follows:

$$Z(\lambda) = C \int \mathcal{D}x \mathcal{D}p e^{-\beta H[x,p,\lambda]},$$  

where the fictitious Hamiltonian is given by

$$H[x,p,\lambda] = \int_{0}^{1} du \left[ \frac{p^{2}}{2m} + \frac{1}{2} \kappa \left( \frac{dx}{du} \right)^{2} + \frac{1}{2} m \dot{\lambda}^{2} \right].$$  

Here $u = s/(\beta \omega)$ is a scaled imaginary time variable and the string tension is

$$\kappa = \frac{m}{\beta^{2} \omega^{2}}.$$  

We are interested in a Hamiltonian process, with equations of motion

$$\frac{\partial \dot{x}}{\partial t} = \frac{\delta H[x,p,\lambda]}{\delta p(u)} = \frac{p}{m}.$$  

in which $\lambda$ is time dependent, and satisfies the boundary conditions $\lambda(0) = \lambda_A$ and $\lambda(T) = \lambda_B$. Then, defining the fictitious work as

$$W = H[x(\tau), p(\tau), \lambda_B] - H[x, p, \lambda_A],$$  

the following identities were shown to hold [1]:

$$\langle e^{-\beta W} \rangle_{\lambda} = e^{-\beta \Delta F},$$  

and

$$P_{\lambda}(W) = e^{\beta W} e^{-\beta F} P_{\lambda}(-W),$$  

where $\langle \rangle_{\lambda}$ denotes an average over nonequilibrium trajectories whose initial conditions are drawn from a canonical distribution with $\lambda = \lambda_A$, $\Delta F = F(\lambda_B) - F(\lambda_A)$, $P_{\lambda}(W)$ is the probability density to do an amount of work $W$ during the process that takes $\lambda$ from $\lambda_A$ to $\lambda_B$ (the forward process), and $P_{\lambda}(-W)$ is the probability density to do work $-W$ during a similar process that starts at $\lambda_B$ and ends at $\lambda_A$ (the reverse process). Equations (9) and (10) are the Jarzynski’s nonequilibrium work relation and Crooks fluctuation relation, respectively.

The distribution of the work done as a result of the change in $\omega$ will be studied for this model. This distribution can be used either in the Jarzynski relation (9) or in the Crooks fluctuation relation (10) to determine the free-energy difference, both of which should yield $\Delta F = F_B - F_A = \beta^{-1} \ln[\sinh(\beta \omega_B/2) / \sinh(\beta \omega_A/2)]$.

The work in Eq. (8) is expressed as the difference of the fictitious Hamiltonian at two times. The average value of the fictitious Hamiltonian diverges in canonical equilibrium due to the infinite number of degrees of freedom in the path integral (2), which might pose a problem for the very definition of the work distributions. To investigate whether the work distribution is well defined, it is necessary to limit the system to a finite number of degrees of freedom. In Ref. [1], two different regularization methods of reducing the path-integral representations to a finite number of dimensions were introduced. While both schemes are similar in their Fourier representations, in one case the degrees of freedom correspond to low-frequency modes of the continuous closed string, whereas in the other case they represent a discretized lattice version of the string. In the first case the regularization is based on statistical arguments motivated by the form of the resulting Hamiltonian, and in the second case the regularization is introduced in the lattice representation by means of the Trotter formula.

For finite $M$, the value of $\Delta F$ found using the work distribution differs from the exact quantum result. In fact, for the harmonic oscillator, one can express the free energy explicitly as an expansion in inverse powers of $M$, and thus assess the convergence of $\Delta F$ analytically. This will be studied first in Sec. III, in which alternative regularizations aimed at improving the convergence are also discussed. Note that the convergence of the free energy only requires equilibrium considerations. Then, in Secs. V–VII, the convergence of the nonequilibrium work distributions is analyzed for the cases...
of an infinitely slow switching rate, a finite switching rate, and an instantaneous switching process, respectively.

III. FREE ENERGY UNDER DIFFERENT REGULARIZATIONS

Analytical considerations of the harmonic system proceed most easily in the Fourier representation. As explained in Ref. [1], the Fourier transformation takes on slightly different forms in the Fourier and the bead regularization methods. In both cases, though, the Hamiltonian assumes the form

$$ H = \sum_{|k| \leq k_c} H_k, $$

(11)

where \( k_c \) is a cutoff wave vector, and

$$ H_k = \frac{\beta^2 k^2}{2m} + \frac{1}{2} m \Omega_k^2 |\vec{x}_k|^2, $$

(12)

with

$$ \Omega_k^2 = \omega_k^2 + \omega^2. $$

(13)

The dispersion relation for the Fourier regularization is given by

$$ \omega_k = 2\pi k \sqrt{\frac{k^2}{m} - \frac{2\pi k}{h\beta}}, $$

(14)

while that for the bead regularization is

$$ \omega_k = \frac{2M}{h\beta} \sin \frac{\pi k}{M}. $$

(15)

Note that in the Fourier regularization, \( k_c \) is a chosen cutoff, whereas from the Fourier transformation of the bead regularization, we have \( k_c = \lfloor (M-1)/2 \rfloor \) or, for \( M \) odd, \( k_c = 2k_c + 1 \). Thus, the two regularization methods can be parametrized either by \( k_c \) or \( M \).

Given the Hamiltonian in Eq. (12), the partition sum may be written as

$$ Z_M(\lambda) = C \prod_{|k| \leq k_c} d\vec{p}_k d\vec{x}_k e^{-\beta H_k}, $$

(16)

where \( C \) is independent of \( \lambda \). Each integral is Gaussian and can be explicitly evaluated. Since each mode occurs twice in the product (as \( k \) and \( -k \)) except for \( k=0 \), one finds for \( e^{-\beta \Delta F} \),

$$ e^{-\beta \Delta F} = \lim_{M \to \infty} Z_M(\lambda_B) = \lim_{k_c \to \infty} \frac{\omega_A}{\omega_B} \prod_{k=1}^{k_c} \frac{\omega_k^2 + \omega^2}{\omega_k^2 + \omega_B^2}, $$

(17)

This product must be evaluated separately for the two different dispersion relations of the Fourier and the bead regularization schemes in Eqs. (14) and (15), respectively.

In the Fourier regularization with the dispersion relation given by Eq. (14), Eq. (17) can be evaluated in the limit \( k_c \to \infty \) by writing

$$ e^{-\beta \Delta F} = \omega_A^{\infty} \prod_{k=1}^{k_c} \left[ 1 + \left( \frac{\beta h \omega_A}{2\pi k} \right)^2 \right]^{-1} \prod_{k'=1}^{k_c} \left[ 1 + \left( \frac{\beta h \omega_B}{2\pi k'} \right)^2 \right]^{-1}, $$

and using the identity [10]

$$ \frac{\sinh z}{z} = \prod_{k=1}^{\infty} \left( 1 + \frac{z^2}{k^2 \pi^2} \right), $$

to finally obtain the exact quantum result

$$ e^{-\beta \Delta F} = \frac{\sinh(\beta h \omega_A/2)}{\sinh(\beta h \omega_B/2)}. $$

(19)

It is straightforward to show using Eq. (17) that the limit is approached as \( k_c^{-1} = O(M^{-1}) \).

For the bead regularization, on the other hand, one uses Eq. (15) and \( M = 2k_c + 1 \) to write Eq. (17) as

$$ e^{-\beta \Delta F} = \lim_{M \to \infty} \left[ \prod_{k=1}^{M} \frac{\sin^2 \frac{\pi k}{M} \left( \frac{h \omega_A}{M} + \frac{\beta h}{2M} \right)^2}{\sin^2 \frac{\pi k}{M} \left( \frac{h \omega_B}{M} + \frac{\beta h}{2M} \right)^2} \right]^{1/2} \left[ \prod_{k=1}^{M} \left( \frac{2 + \left( \frac{h \omega_A}{M} \right)^2 - 2 \cos \frac{2\pi k}{M}}{2 + \left( \frac{h \omega_B}{M} \right)^2 - 2 \cos \frac{2\pi k}{M}} \right) \right]^{1/2}. $$

(20)

One then uses a different identity, namely [11],

$$ \frac{1}{2} \prod_{k=1}^{M} \left( z - 2 \cos \frac{2\pi k}{M} \right) = \cosh \left( M \arccosh \frac{z}{2} \right) - 1, $$

(21)

to arrive at

$$ e^{-\beta \Delta F} = \lim_{M \to \infty} \left[ \cosh \left( M \arccosh \left[ 1 + \frac{1}{2} \left( \frac{h \omega_A}{M} \right)^2 \right] \right) - 1 \right]^{1/2} \left[ \cosh \left( M \arccosh \left[ 1 + \frac{1}{2} \left( \frac{h \omega_B}{M} \right)^2 \right] \right) - 1 \right]^{-1}, $$

(22)

which reduces to Eq. (19) as well when the limit \( M \to \infty \) is evaluated, with correction terms of order \( M^{-2} \) (see, e.g., Ref. [11]).

There are other regularization methods possible which lead to even faster convergence of the free energy at the expense of a more complicated regularized Hamiltonian. Such higher-order schemes can be derived systematically by exploiting the analogy between the bead representation and the Hamiltonian-splitting method used to obtain integrators in molecular dynamics. In fact, the basis of the bead regularization is the splitting form in Eq. (30) of the preceding paper [1], and that same form is also the basis of the Verlet scheme to integrate the equations of motion for classical Hamiltonian systems in molecular dynamics simulations [12]. The advantage of using splitting schemes to derive integrators for molecular dynamics is that the approximate dy-
namics is still symplectic, causing such integration schemes to be very stable. The analogous property to symplecticity in the path-integral context is the Hermitian nature of the Boltzmann operator, which is preserved in splitting schemes.

In an attempt to reduce the error due to operator splitting, many alternative splitting schemes for molecular dynamics simulations have been derived (see Ref. [13], and references therein). Some of these schemes raise the order of the splitting approximation to $O(\delta t^2)$ or higher. Such splitting schemes can also be used for path integrals and result in a fictitious Hamiltonian in which the beads are not all equivalent or which contains explicit correction terms of order $O(\delta t^2)$ in the potential, and whose partition function converges to the real quantum partition sum as $O(M^{-4})$ or higher. Other splitting schemes derived for molecular dynamics simulations are aimed at reducing the error by minimizing the prefactors in front of the leading correction terms [14]. These methods, however, are based on the assumption that different correction terms contribute independently and equally to the error. This approach has proved useful in molecular dynamics simulations of rigid water molecules [15].

We will briefly consider the HOA2 operator-splitting scheme applied as a means to regularize imaginary-time path integrals, since it is the simplest splitting method that may improve the rate of convergence of the regularization. It is based on the following operator-splitting scheme:

$$e^{-\beta \hat{H}/M} = e^{-\eta \hat{V}/M} e^{\beta \hat{U}/(2M)} e^{-(1-2\eta) \hat{V}/(2M)} e^{-\beta \hat{U}/(2M)} e^{-\eta \hat{V}/M} + O(M^{-3}).$$  (23)

For $\eta = 1/4$, this splitting scheme reduces to the path-integral analog of the Verlet scheme of molecular dynamics (applied twice), which corresponds to the standard bead regularization procedure. However, taking a different value of $\eta$, namely, $\eta = 0.193\ 183\ 327\ 503\ 783\ 6$, minimizes the sum of the squares of the error terms of $O(M^{-3})$ [14]. It is shown in Appendix A that when applied to the dynamics of a classical harmonic oscillator, this scheme conserves energy better than the Verlet scheme. The application of the HOA2 splitting scheme to path integrals is carried out by representing the Boltzmann operator by $M$ factors of $\exp(-\beta \hat{H}/M)$, taking its trace to get the partition function, using the splitting scheme (23) for each factor, inserting completeness relations between each exponential, and performing the momentum integration. This procedure leads to a regularized path integral with Hamiltonian

$$H_M = \sum_{n=1}^M \left\{ \frac{mM}{\beta^2} \left[ (u_n - u_{n+1})^2 + (u_{n+1} - v_n)^2 \right] + \frac{1}{2M} \left[ w_1 U(u_n) + w_2 U(v_n) \right] \right\}. $$  (24)

Here, $w_1 = 4\eta$, $w_2 = 2 - 4\eta$ and the $u_n$ and $v_n$ are the positions of the odd and the even beads, respectively. Odd and even beads are no longer identical in nature when $\eta \neq 1/4$ because the completeness relation inserted either in front of the $e^{-(1-2\eta) \hat{V}/(2M)}$ or the $e^{-\eta \hat{V}/M}$ in Eq. (23) gives rise to different potential strengths $w_2$ and $w_1$. The partition sum $Z_M = \int d^M \mu \exp(-\beta \hat{H}/M)$ is of Gaussian form, since $H_M$ can be written as $H_M = \Gamma^\dagger \Gamma$, with $\Gamma = (u_1, v_1, u_2, v_2, \ldots)$. The integral can be evaluated in terms of the determinant of the matrix $V$. For the Verlet-type Hamiltonian, a Fourier transform could be used to diagonalize the matrix (i.e., to decouple the modes), which facilitates the determination of the eigenvalues and thus the determinant of $V$. Here, a Fourier transform only yields a partial diagonalization, i.e., defining

$$u_k = \frac{1}{\sqrt{2M}} \sum_{n=1}^M e^{-2\pi i k n / M} u_n e^{-\pi i k / M v_n},$$

the factor $\sqrt{2}$ and the shift in the phase in front of $v_n$ are introduced for convenience), one gets

$$H_M = \sum_{k=1}^M (\tilde{u}_k \hat{v}_k) W_k (\tilde{u}_k \hat{v}_k)^{\dagger},$$  (26)

with

$$W_k = \frac{4M^2}{\beta^2 \hbar^2} \left( 2 + w_1 \left( \frac{\beta \hbar \omega}{2M} \right)^2 - 2 \cos \frac{\pi k}{M} \right) \left( 2 + w_2 \left( \frac{\beta \hbar \omega}{2M} \right)^2 \right).$$

Since each term in the Hamiltonian is simply a $2 \times 2$ quadratic form, the partition sum can be written as a product of two-dimensional Gaussian integrals, each of which is proportional to $1/\sqrt{\det W_k}$. The finite-$M$ partition sum thus becomes

$$Z_M = \prod_{k=1}^M \left[ 2 + 4 \left( \frac{\beta \hbar \omega}{2M} \right)^2 + w_1 w_2 \left( \frac{\beta \hbar \omega}{2M} \right)^4 - 2 \cos \frac{2\pi k}{M} \right]^{1/2}.$$  (27)

Using the identity in Eq. (21) gives the result
By expanding $Z_M$ in $M$, one can write this as

$$Z_M = \frac{1}{2 \sinh(\beta h \omega/2)} \left[ 1 + \frac{z(\eta) (\beta h \omega/2)^3}{\tanh(\beta h \omega/2) M^2 + O(M^{-4})} \right].$$

where the prefactor for the first correction term is $z(\eta) = 1/6 - \eta + 2 \eta^2$. Thus, different values of $\eta$ lead to different convergence properties since $z(\eta)$ depends explicitly on $\eta$. The leading order correction is minimized by choosing $z(\eta) = 0$, i.e., $\eta = 1/4$, which corresponds to the standard bead regularization procedure. Other choices for $\eta$ lead to larger correction terms and hence slower convergence.

We therefore conclude that using a different splitting scheme can be useful for path integrals if the order of the approximation is changed, but that optimized splitting methods need not yield any improvement, even if they have been shown to be beneficial in the context of molecular dynamics simulations. We will therefore work only with the Verlet-type Hamiltonian in the remainder of this paper.

### IV. GENERATING FUNCTION OF THE WORK DISTRIBUTION

The calculation of the work distribution proceeds most easily by first determining its generating function (which coincides with its Fourier transform)

$$G(u) = \int_{-\infty}^{\infty} dW e^{iuW} P(W)$$

where $H(t) = H(\tilde{x}(t), \tilde{p}(t), \lambda(t))$, which in this case can be written as in Eq. (11).

The equations of motion are given by

$$\frac{d\tilde{x}_k}{dt} = \frac{\tilde{p}_k}{m},$$

$$\frac{d\tilde{p}_k}{dt} = -m \Omega_\lambda^2(t) \tilde{x}_k.$$ (31b)

From the equations of motion, it is apparent that all Fourier modes evolve independently with a time-dependent frequency, and that each mode contributes an independent term

$$W_k = H_k(\tau) - H_k(0)$$

(32)

to the total work $W = \sum_{\lambda \leq \lambda} W_k$. Furthermore, the modes are also independent in the initial canonical distribution function $\exp[-\beta H(\tilde{x}, \tilde{p}, \omega_\lambda^2)]$. Because the generating function of the sum of independent terms is the product of the generating functions of the different terms, we get for $G(u)$

$$G(u) = \prod_{\lambda \leq \lambda} G_k(u),$$

where

$$G_k(u) = \int dx e^{iuW} e^{-\beta H_k(0)} \int dx e^{iux} e^{-\beta H_k(0)}.$$ (34)

Below, we will investigate the convergence of the work distribution functions $P_f$ and $P_r$ as $M$ is taken to infinity.

### V. QUASISTATIC PROCESS

#### A. Work distribution

Consider first a process in which $\omega$ is changed infinitely slowly or quasistatically from $\omega_A$ to $\omega_B$. Since each mode $k$ is equivalent to a classical harmonic oscillator with frequency $\Omega_\lambda$, and $\Omega_k$ changes from $\omega_A(\tau) = \sqrt{\omega_A^2 + \omega_H^2}$ to $\omega_B(\tau) = \sqrt{\omega_B^2 + \omega_H^2}$, one can use that $H_k(\tau)/\Omega_k(\tau)$ is an adiabatic invariant for harmonic oscillators [16], to obtain for the work

$$W_k = [\Omega_k(\tau)/\Omega_k(0) - 1] H_k(0).$$ (35)

Equation (34) then gives for the generating functions of mode $k$,

$$G_k(u) = \frac{1}{1 - i u / \gamma_k}.$$ (36)

where

$$\gamma_k = \beta \left[ \omega_A^2 + \omega_H^2 - \sqrt{\omega_A^2 + \omega_H^2} \right]^{-1}.$$ (37)

Note that all $\gamma_k$ have the same sign as $\omega_B - \omega_A$, cf. Eq. (37). The inverse Fourier transform of Eq. (36) is

$$P_k(W) = |\gamma_k| e^{-\gamma_k \Theta(\gamma_k W)},$$ (38)

where $\Theta$ is the Heaviside step function. The inverse Fourier transform of $G(u)$ in Eq. (33) is a convolution of these exponential functions, which yields

$$P(W) = \Theta(\gamma_0 W) \sum_{k=0}^{\infty} \Gamma_k(W) e^{-\gamma_k W},$$ (39)

where the form of $\Gamma_k(W)$ depends on whether mode $k$ is degenerate or not. For degenerate modes with $\gamma_k = \gamma_{-k}$ (i.e., $1 \leq k = \lfloor M/2 \rfloor$), $\Gamma_k(W)$ is a linear function of $W$.
converge by analyzing the cumulants of the distributions, rather than the somewhat cumbersome infinite products and sums in Eqs. (40a) and (40b). The cumulants $\kappa_j$ of the distribution $P(W)$ follow from the generating function as

$$\kappa_j = \left[ \frac{d}{d(iu)} \right]_0^\infty \ln(G(u)), \quad (41)$$

which means the generating function can be expressed in terms of cumulants as

$$\ln(G(u)) = \sum_{j=1}^\infty \frac{\kappa_j}{j!} (iu)^j. \quad (42)$$

The cumulants are therefore also formally related to the free-energy difference by the Jarzynski relation (9), i.e.,

$$\Delta F = -\frac{1}{\beta} \ln(e^{-\beta W}) = -\frac{1}{\beta} \ln(G(i\beta)) = \sum_{j=1}^\infty \frac{\kappa_j}{j!} (-\beta)^{j-1}. \quad (43)$$

Cumulants of independent variables are additive, so that

$$\kappa_j = \sum_{|k| \neq k}\kappa_j^{(k)} = \sum_{|k| \neq k} \frac{(j-1)!}{\gamma^j_k}, \quad (44)$$

where the mode cumulants were determined from Eq. (36). The convergence of the cumulants as $k_c \rightarrow \infty$ can be determined now. From Eq. (37), one sees that

$$\gamma_k = \frac{2\beta \omega_k}{\Delta \omega^2}, \quad (45)$$

where

$$\Delta \omega^2 = \omega^2_A - \omega^2_B, \quad (46)$$

and therefore

$$\kappa_j^{(k)} (\Delta \omega^2)_{2\beta \omega_k} \sim (j-1)! \left(\frac{\Delta \omega^2}{2\beta \omega_k}\right)^j. \quad (47)$$

The effect of this asymptotic formula is different in the Fourier and in the bead regularization. In the Fourier regularization, $\omega_k \sim k$, so that $\kappa_j^{(k)} \sim 1/k^j$. Thus one sees that not only do all cumulants in Eq. (44) converge as $k_c \rightarrow \infty$, higher-order cumulants converge faster than lower orders, i.e.,

$$\kappa_j(k_c) - \kappa_j(\infty) = O(1/k^{j-1}_c) = O(1/M^{j-1}). \quad (48)$$

This means that the shape of the work distribution converges faster than the average. However, this property turns out not to be robust. One can show that adding a perturbative quartic term to the potential causes all cumulants to converge as $k_c^{-1}$ in the Fourier regularization [17].

The asymptotic convergence of the cumulants is different in the bead regularization scheme, as is evident when the sum in Eq. (44) is first split up into a sum from $k = -k^*$ to $k^*$ and a sum of modes with $k^* \leq |k| \leq k_c = M/2$, and the latter is approximated by an integral as follows:

$$\ln(G(u)) = \sum_{j=1}^\infty \frac{\kappa_j}{j!} (iu)^j. \quad (42)$$
Thus all cumulants in the bead regularization converge as $M \to \infty$. Using Eq. (15), one gets

$$\frac{\kappa_j - C_j}{2(j-1)!} \sim \left( \frac{\beta \hbar^2 \Delta \omega^2}{8 \pi^2} \right)^j M^{j/2} \frac{dq}{k^{j/2} \sin^2(\pi q)}$$

leading to

$$\frac{\kappa_j - C_j}{2(j-1)!} \sim \left( \frac{\beta \hbar^2 \Delta \omega^2}{8 \pi^2} \right)^j \frac{1}{2j-1} k^{2j-1} + O(M^{-2}).$$

(51)

Thus all cumulants in the bead regularization converge as $1/M^2$. Note that this behavior is consistent with the numerical results presented in Fig. 3 of the preceding paper [1].

Even though all cumulants converge in the same way, the coefficients in front of the $1/M^2$ terms often turn out to get smaller for higher-order cumulants, so that the shape will still appear to converge rather quickly, as Fig. 3 illustrates: for large enough $M$, the shapes of the forward work distributions for different values of $M$ are very similar, but shifted along the $W$ axis.

Since the cumulants of the work distribution converge in the limit $M \to \infty$ in both regularization schemes, the work distribution itself is well defined and converges as $M^{-1}$ or $M^{-2}$ for the Fourier and the bead regularizations, respectively, in spite of the fact that the average energy $\langle H \rangle$ diverges linearly with $M$.

C. Convergence of the Jarzynski relation

We will end this section with an explicit demonstration that Jarzynski’s nonequilibrium work relation is obeyed and converges to the correct quantum result in the limit $M \to \infty$.

First note from Eq. (29) that the left-hand side of Eq. (9) may be reformulated as $\langle \exp(-\beta W) \rangle_{\lambda_i} = G(i\beta)$. Using Eqs. (33), (36), and (37), one finds

$$\langle \exp(-\beta W) \rangle = \frac{\omega_A}{\omega_B} \prod_{k=1}^{\Omega} \frac{\omega_A^2 + \omega_k^2}{\omega_k^2 + \omega_B^2}.$$

(52)

This product coincides with the product on the right-hand side of Eq. (17), showing that the Jarzynski equality $\langle \exp(-\beta W) \rangle = e^{-\Delta F}$ holds and that the resulting free-energy difference converges to the exact result in the limit $M \to \infty$ in the same way, i.e., as $1/M$ for the Fourier regularization and as $1/M^2$ for the bead regularization, as expected from Eqs. (43), (48), and (51).

VI. FINITE SWITCHING SPEED

A. Work distribution

Consider now the case in which the switch from $\omega_A$ to $\omega_B$ is done in a finite (fictitious) time $\tau$, using the protocol

$$\omega^2(t) = \omega_A^2 + \Delta \omega^2 \frac{t}{\tau},$$

(53)

where $\Delta \omega^2$ was defined in Eq. (46), so that $\omega^2(\tau) = \omega_B^2$.

As in the quasistatic process, the Fourier modes are independent and can be handled separately using a time-dependent frequency $\Omega_k(t)$ defined through Eqs. (13) and (53). The solution of Eqs. (31a) and (31b) for a set of initial conditions $X_k(0) = (\bar{X}_k(0), \bar{P}_k(0))$ for this switching protocol can be written as a linear mapping

$$X_k(t) = M_k(t)X_k(0),$$

(54)

where $\det M_k(t) = 1$ since the dynamics conserves phase-space volume. The mapping matrix $M_k(t)$ can be written explicitly in terms of the Airy functions [18] $\phi_i(t) = \text{Ai}[\Omega^2_k(t)/b]$ and $\phi_2(t) = \text{Bi}[\Omega^2_k(t)/b]$ with $b = (|\Delta \omega^2|/\tau)^{2/3}$ as

$$M_k(t) = \tilde{M}_k(t)\tilde{M}_k^{-1}(0),$$

(55)

where

$$\tilde{M}_k(t) = \left( \begin{array}{cc} \phi_1(t) & \phi_2(t) \\ m\phi_1(t) & m\phi_2(t) \end{array} \right),$$

(56)

which yields

$$M_k(t) = \left( \begin{array}{c} \text{Ai}(-y_i)\text{Bi}'(-y_0) - \text{Bi}(-y_i)\text{Ai}'(-y_0) \\ \sigma \text{Ai}(-y_i)\text{Bi}'(-y_0) - \text{Bi}(-y_i)\text{Ai}'(-y_0) \end{array} \right) - \frac{\sigma}{m\sqrt{b}} \left( \text{Ai}(-y_i)\text{Bi}'(-y_0) - \text{Bi}(-y_i)\text{Ai}'(-y_0) \right),$$

(57)

where $\sigma = \pm 1$ depending on the sign of $\Delta \omega^2$, $y_i = \Omega^2_k(t)/b$, and $\text{Ai}'$ and $\text{Bi}'$ are the derivatives of the Airy functions.
Defining a diagonal matrix
\[
D_k(t) = \begin{pmatrix}
\frac{1}{2}m\Omega_k^2(t) & 0 \\
0 & \frac{1}{2m}
\end{pmatrix},
\]

the energy contribution of mode \(k\) at time \(t\) can be written as
\[
H_k(t) = X_k^T(t)D_k(t)X_k(t) = X_k^T(0)H_k(0)X_k(0),
\]

where the “Hamiltonian” matrix is given by
\[
H_k(t) = M(t)D_k(t)M(t).
\]

From Eq. (12), the work contribution of mode \(k\) can then be written as
\[
W_k = X_k^T(0)[H_k(\tau) - D_k(0)]X_k(0),
\]

where we used that \(H_k(0) = D_k(0)\). It is now straightforward to compute the generating function \(G_k(u)\) of \(W_k\),
\[
G_k(u) = \frac{\int dX_k(t)e^{X_k^T(0)i[H_k(\tau) - D_k(0)]X_k(0)}}{\int dX_k(t)e^{-\beta X_k^T(0)D_k(0)X_k(0)}}
= \left[\text{Det}(1 - iu/C_k)\right]^{-1/2},
\]

where \(C_k = D_k^{-1/2}(0)H_k(\tau)D_k^{-1/2}(0) - I\).

To illustrate the dependence of the work distributions on \(\tau\), we need to perform the Fourier inverse on \(G(u) = \Pi_k G_k(u)\). For \(|k| > 0\), this is simple, since \(k\) and \(-k\) are degenerate and yield the combined contribution
\[
G_k^{\Pi}(u) = \frac{1}{\text{Det}(1 - iu/C_k)} = \frac{1}{1 - iu\lambda_k^{(1)}\lambda_k^{(2)}},
\]

where \(\lambda_k^{(1)}\) and \(\lambda_k^{(2)}\) are the two eigenvalues of \(C_k\). The right-hand side of Eq. (62) has the form of two independent exponential modes with rates \(\beta/\lambda_k^{(1,2)}\). The Fourier inverse of \(\sum_{0<|k|<k_x} G_k^{\Pi}(u)\) is therefore

\[
\tilde{P}(W) = \Theta(\gamma_0 W)\sum_{k=1}^{2k_x} \prod_{q=1}^{k} \left(\frac{1 - \gamma_q}{\gamma_q}\right)^{-1} e^{-\gamma_q W},
\]

where by definition \(\lambda_k^{(1)} = \beta/\gamma_{k(0,1)+}\) and \(\lambda_k^{(2)} = \beta/\gamma_{k(0,2)}\), and whose Fourier inverse is given by
\[
P_0(W) = \sqrt{\gamma_{+} \gamma_{-} \gamma_{+}^{2}} W I_0\left(\frac{\gamma_+ + \gamma_-}{2} W\right),
\]

where \(I_0\) is the zeroth-order modified Bessel function of the first kind. The derivation of this result, which holds when \(\gamma_+\) and \(\gamma_-\) are both positive, is given in Appendix B. In fact it can be shown that for monotonically increasing \(\omega\), such as in Eq. (53), \(\gamma_+\) and \(\gamma_-\) must always be positive, though this restriction need not hold for more complicated protocols.

The complete work distribution function is therefore
\[
P(W) = \int_0^W dW' P_0(W') \tilde{P}(W - W'),
\]

which unfortunately does not lead to a closed form, but can easily be computed numerically since \(P_0\) and \(\tilde{P}\) are known analytically. As an example, the resulting \(P(W)\) for the same parameters as for the quasistatic case is shown in Fig. 4 for \(\tau = 3/2\), both for the forward and reverse process.
B. Convergence of the work distribution

To determine the convergence properties of the work distribution as $M \to \infty$, we will once again use the cumulants of the work. From the generating function in Eq. (60), we have

$$\sum_{j=1}^{\infty} \frac{(iu)^j}{j!} \kappa_j^{(k)} = -\frac{1}{2} \ln(1 - \frac{i u}{\beta C_k}).$$  \hspace{1cm} (66)

By expanding the logarithm and equating like powers of $u$ for $j \gg 1$, one finds the cumulants of the different modes to be

$$\kappa_j^{(k)} = \frac{(j-1)!}{2\beta^j} \text{Tr} C^j_k.$$  \hspace{1cm} (67)

One thus has for the cumulants of the total work,

$$\kappa_j = \frac{(j-1)!}{2\beta^j} \sum_{k=1}^{\infty} \text{Tr} C^j_k.$$  \hspace{1cm} (68)

This is of similar form to the expression (44) for the work cumulants in the quasistatic process, which could be shown to converge because of the asymptotic property of $\gamma_k$ as $k \to \infty$ in Eq. (45). A similar asymptotic property here has to involve the two eigenvalues $\lambda_0^{(k)}$ and $\lambda_2^{(k)}$ of the real symmetric $2 \times 2$ matrix $C_k$ for large $k$. This asymptotic analysis starts with the behavior of the Airy functions for large negative arguments [18]

$$\text{Ai}(-y) \sim \frac{\sin\left(\frac{2}{3}y^{3/2} + \frac{\pi}{4}\right)}{\pi^{1/2}y^{1/4}},$$  \hspace{1cm} (68a)

$$\text{Bi}(-y) \sim \frac{\cos\left(\frac{2}{3}y^{3/2} + \frac{\pi}{4}\right)}{\pi^{1/2}y^{1/4}},$$  \hspace{1cm} (68b)

$$\text{Ai}'(-y) \sim -\frac{\cos\left(\frac{2}{3}y^{3/2} + \frac{\pi}{4}\right)}{\pi^{1/2}y^{1/4}},$$  \hspace{1cm} (68c)

$$\text{Bi}'(-y) \sim -\frac{\sin\left(\frac{2}{3}y^{3/2} + \frac{\pi}{4}\right)}{\pi^{1/2}y^{1/4}},$$  \hspace{1cm} (68d)

with corrections of relative $O(y^{-3/2})$. Using these asymptotic expressions, one can write for the mapping matrix needed in Eq. (61),

$$\mathbf{M}_k(\tau) \sim \begin{pmatrix} \frac{1}{\eta_k} \cos \theta_k & \frac{1}{\eta_k \mu \Omega_1(0)} \sin \theta_k \\ -\frac{1}{\eta_k \mu \Omega_1(0)} \sin \theta_k & \frac{\eta_k \cos \theta_k}{} \end{pmatrix},$$  \hspace{1cm} (69)

with $\theta_k = \frac{\pi}{2}(y_\tau^{-1} - y_0^{-1})$ and $\eta_k = \sqrt{\Omega_1(\tau)/\Omega_1(0)}$. Substituting this $\mathbf{M}_k(\tau)$ into Eq. (59) for $\mathbf{H}_k$ using $\Omega_1(\tau) = \eta_k^2 \Omega_1(0)$ in $\mathbf{D}_k(\tau)$, and substituting the result into expression (61) for $C_k$, yields

$$C_k \sim \langle \eta_k^2 - 1 \rangle.$$

Thus it is clear that asymptotically, both eigenvalues of $C_k$ are equal to $\lambda_1^{(k)} = \lambda_2^{(k)} = \eta_k - 1$. But $\eta_k - 1$ is precisely equal to $\beta/\gamma_k$, so that Eq. (67) gives

$$\kappa_j^{(k)} = \frac{(j-1)!}{\beta^j} \left( \frac{\beta}{\gamma_k} \right)^j = (j-1)!,$$

which precisely coincides with the asymptotic expression of the cumulants of mode $k$ in the quasistatic case, Eq. (44). In retrospect, this is not too surprising: higher $k$ modes have higher frequencies $\Omega_k$, so that the relative switching speed $1/(\tau \Omega_k)$ decreases for increasing $k$, resulting in a quasistatic behavior for the work distributions of the high-$k$ modes.

Since the behavior of the work cumulants for large $k$ is the same as in the quasistatic switching, the cumulants themselves converge for the finite-switching speed as well, and in exactly the same way, i.e., $O(1/M^2)$ in the Fourier regularization and $O(1/M^2)$ for the bead regularization. However, it should be stressed that the correspondence between the quasistatic and finite-switching case only holds for the large $k$ modes, and that the lower $k$ modes do differ between the two cases and the total work distribution can vary substantially depending on the switching speed.

C. Convergence of the Jarzynski relation

With these results for the generating function, the Jarzynski equality (9) can be once more checked. Setting $u = i \beta$ in Eq. (60), the generating function gives

$$G_k(i\beta) = \left( \frac{\text{Det } \mathbf{D}_k(0)}{\text{Det } \mathbf{H}_k(\tau)} \right)^{1/2} \left( \frac{\text{Det } \mathbf{D}_k(\tau)}{\text{Det } \mathbf{H}_k(\tau)} \right)^{1/2} = \frac{\Omega_k(0)}{\Omega_k(\tau)},$$  \hspace{1cm} (71)

where the fact that $\text{Det } \mathbf{M}(\tau) = 1$ has been used. Putting together all the contributions to $G(\beta)$, one obtains the same expression as for the quasistatic case, Eq. (52). The subsequent calculation therefore applies, showing that the Jarzynski relation, Eq. (9), in the form of Eq. (19), also holds for finite-switching rates.

The result in Eq. (19) holds not only for any $\tau$ using the protocol in Eq. (53), but in fact for any protocol. A different Hamiltonian dynamics would only change the linear mapping $\mathbf{M}_k(\tau)$, which would still obey $\text{Det } \mathbf{M}_k(\tau) = 1$, since this follows purely from the Hamiltonian nature of the dynamics. Thus, Eq. (71) would still hold, from which the Jarzynski relation follows.

VII. INSTANTANEOUS SWITCHING

While the work distribution for finite $\tau$ could only be expressed analytically up to a convolution, for $\tau = 0$, it is possible to derive a fully analytical form. In this instantaneous limit, the system does not have time to change its positions or momenta, whence $W_1 = \frac{1}{2} m \Delta \omega \dot{x}_0^2 / \gamma_0^2$. This allows the generating function $G_k(u)$ to be computed, leading to
The generating function can be inverted, to yield
\[
\tilde{P}(W) = \Theta(\gamma_0^2 W) \sum_{k=1}^{\infty} \frac{|\gamma_0^2 \text{erfi}(\gamma_0^2 W)|^{k-1}}{\sqrt{\pi}^{k-1} (k-1)!} e^{-\gamma_0^2 W},
\]
(73)
where \(\gamma_0^2 = \beta \Omega_k^2 / \Delta \omega^2\) and \(\text{erfi}(x) = -i \text{erf}(ix)\) is the complex error function. This work distribution \(\tilde{P}(W)\) has also been plotted in Fig. 4, for the same parameters as for the quasi-static and finite-\(\tau\) cases and both for the forward and reverse process. One sees that regardless of the speed of the process, the crossing points \(W_c\) of the forward and reverse distributions are all the same, and equal to the free-energy difference.

To check the convergence of the Jarzynski equality in the instantaneous switching case, one substitutes \(u = i\beta\) into Eq. (72). For each of the modes, the generating function at \(u = i\beta\) coincides with the result for the finite-switching speed, i.e., the right-hand side of Eq. (71). As a result, the convergence of the free energy as computed from the Jarzynski equality in the instantaneous case is the same as it was for the finite-switching case, as would be expected since the former is the \(\tau \to 0\) limit of the latter.

The convergence of the work distribution might be expected to follow similarly by taking the limit \(\tau \to 0\) of the cumulants found in the case of finite switching, but it turns out that the limits \(\tau \to 0\) and \(k \to \infty\) do not commute. The physical reason is that no matter how fast the finite switching is, for fixed positive definite \(\tau\) and growing \(k\), there are always \(k\) modes whose frequencies \(\Omega_k\) are faster than the switching rate \(\tau^{-1}\), and for those modes the switching is nearly quasi-static. But if \(\tau \to 0\), then the process is instantaneous for all modes, regardless of their \(k\) value.

To see the noncommutativity of the limits mathematically, note that for an instantaneous process in which the positions and momenta of the system do not have time to change, the \(M_k(\tau)\) matrix is equal to the identity matrix. The matrix \(C_k\) defined in Eq. (61) then assumes the form
\[
C_k = \begin{pmatrix}
\Omega_B^2 - 1 & 0 \\
0 & 0
\end{pmatrix},
\]
(74)
where \(\Omega_k^2 = \omega_k^2 + \omega_0^2\) and \(\Omega_k^2 = \lim_{\tau \to 0} \Omega_k^2(\tau) = \omega_k^2 + \omega_0^2\). This form is not the same as the \(\tau \to 0\) limit of Eq. (70). From Eqs. (67) and (74), one finds for the mode cumulants in the instantaneous switching case
\[
\kappa^{(j)} = \frac{(j-1)!}{2\beta^j} \left( \Omega_B^2 - 1 \right) \left( \Omega_A^2 + 1 \right)^j = \frac{(j-1)!}{2\beta^j} \left( \Omega_B^2 - 1 \right) \left( \Omega_A^2 + 1 \right)^j,
\]
(75)
where Eq. (37) was used. For large \(k\), \(\Omega_k^2 / \Omega_A^2 + 1 \to 2\), so that \(\kappa^{(j)} \approx \gamma_j^2\) in this regime. Apart from a \(k\) independent prefactor, the asymptotic behavior of the cumulants as a function of \(k\) is the same as in the previous cases, so that the convergence of the work distribution is also the same.

**VIII. COMPARISON WITH REAL TIME QUANTUM DYNAMICS**

The viability of the nonequilibrium path-integral approach for the computation of quantum free-energy differences is made possible by the use of a fictitious dynamic, thus avoiding the problems associated with the description of the real time quantum evolution of the system, in contrast to other extensions of the Jarzynski and Crooks fluctuation relations to the realm of quantum mechanics, based on the operator formulation of quantum dynamics \([19–25]\). As a consequence, however, the work computed within this scheme bears no relation to the work performed in any real quantum process except in the classical limit \(\hbar, \beta \to 0\), where there are no contributions to the work distribution from the nonzero \(k\) modes in the fictitious dynamics. The work distribution for an isolated quantum system in which the frequency is changed in real (rather than fictitious) time has recently been worked out by Defner and Lutz \([25]\), so that a direct comparison between the fictitious dynamics and real quantum dynamics is possible.

The work distribution for the quantum harmonic oscillator consists of a sum of delta functions, since the real quantum work distribution can be obtained by summing over all possible transitions with the appropriate transition amplitudes worked out by Husimi \([26]\). Thus, for the purpose of comparison, it is better to consider the cumulative distribution function (CDF) \(C(W) = \int_0^W dw P(w)\) \([27]\). Figure 5 shows the comparison between the classical CDF \([cf. \ Eq. (64)]\), the quantum CDF (using Husimi’s transition amplitudes), and the CDF resulting from the fictitious path dynamics \([cf. \ Eqs. (63)–(65)]\) for \(\omega_q = 1/2\), \(\omega_0 = 5/4\), \(\tau = 3/2\), and \(\beta = 4\). The three curves are obviously very different. The quantum distribution is composed of steps, while the other two are continuous. The quantum distribution also does not agree with
the fictitious dynamics on average. Interestingly, the deviation of the real quantum dynamics from the classical case is less than the deviation from the fictitious dynamics. Another difference between the real quantum dynamics and the dynamics in the other cases is the nonzero probability of negative work values predicted by the distribution, which, as suggested in Ref. [25], is due to excited states decaying to lower states. This negative tail disappears in the classical limit for the monotonic protocol in Eq. (53). The negative tails in the classical limit found in Ref. [25] can only exist for nonmonotonic protocols. Given these observations, it is clear that the fictitious dynamics is very different from real quantum dynamics and has little direct physical content.

IX. CONCLUSIONS

The nonequilibrium methods for the calculation of free-energy differences in quantum systems in the context of the path-integral representation of the canonical partition function presented in the previous paper were applied to the harmonic oscillator to show that the work distribution function is well defined as the regularization parameter $M$ is taken to infinity. Instead of using the real quantum dynamics of the system, the path-integral representation allows a fictitious path to be defined for which the Jarzynski and Crooks relations are valid. By evolving the ring polymer in the path-integral representation under fictitious dynamics, the difficulties associated with the complexity of the full evolution of a quantum system are avoided.

In particular, expressions for the distribution $P(W)$ of the work $W$ done in the nonequilibrium fictitious process in which the strength changes linearly during a time $\tau$ were derived, in the form of a single convolution for finite $\tau$, and in fully explicit form for $\tau \to 0$ (the instantaneous limit) and $\tau \to \infty$ (the quasistatic limit). From $P(W)$, it was shown that the Jarzynski relation holds for this case for any dynamic switching process based on (isolated) Hamiltonian dynamics. The convergence of the resulting free-energy difference was obtained for both regularizations, and goes as $O(M^{-1})$ for the Fourier regularization and as $O(M^{-2})$ for the bead regularization. The nature of the convergence of the cumulants of $P(W)$ as $M \to \infty$ was also determined for any $\tau$. Whereas the beads regularization leads to cumulants which all converge as $M^{-2}$, the $j$th cumulant converges as $O(M^{1-2j})$ in the Fourier representation, implying that the shape of the distribution converges faster than its position along the $W$ axis. However, one can use perturbative arguments with the harmonic oscillator as the zeroth-order system to show that the work distributions in the Fourier and bead regularization converge as $1/M$ and $1/M^2$, respectively. Indeed, in the path-integral simulations using the bead regularization presented in the preceding paper [1], one sees a $1/M^2$ convergence for the free-energy difference as well as for the first and second cumulant of the work distribution function. Given the analytical proof given in this paper and the numerical evidence in the preceding paper, it can be expected that the convergence of the method is general.

Other regularization schemes based on the splitting method were also briefly considered and it was found that splitting schemes optimized for molecular dynamics need not be optimal for the convergence of path integrals, in contrast to higher-order splitting schemes which will have better asymptotic convergence properties.

The difference between the fictitious dynamics and real quantum dynamics was demonstrated by direct comparison of the work distribution. Not only is the nature of the distribution different (delta peaks for the quantum case, a smooth function for the fictitious dynamics), but the two also do not agree on average. Nonetheless, the free energy found from the nonequilibrium method with fictitious dynamics is the exact quantum free-energy difference.

APPENDIX A: ENERGY CONSERVATION OF THE CLASSICAL HARMONIC OSCILLATOR UNDER THE HOA2 INTEGRATION SCHEME

The HOA2 scheme is a second-order integrator for molecular dynamics simulations, like the Verlet scheme, but contains a parameter $\eta$ which can be tuned to make the dynamics as accurate as possible [13,14,28]. In this appendix, the level of energy conservation as a function of $\eta$ will be determined explicitly for the classical harmonic oscillator.

The state of the classical harmonic oscillator is represented by a position $x$ and momentum $p$. Combining these quantities into a two-dimensional vector $\Gamma=(x,p/m)$, the energy of the oscillator is given by $E=\frac{1}{2}m\Gamma^2$.

In applying the HOA2 splitting scheme in Eq. (23) to molecular dynamics, the kinetic operator $\hat{T}$ is to be replaced by the free Liouville operator $L_T=\frac{p^2}{2m}$, and the potential operator $\hat{V}$ by the interaction Liouville operator...
\( \mathcal{L}_T = \{ V(r), \} \), where \( \{ , \} \) is the Poisson bracket operator. The sum of these two Liouville operators is the full Liouvillian \( \mathcal{L} = \mathcal{L}_T + \mathcal{L}_V \). Because of the linearity of the equations of motion of the classical harmonics oscillator, the exponentials of these two Liouville operators can be written as the matrices

\[
e^{\mathcal{L}_T} = A(t) = \begin{pmatrix} 1 & \tau \\ 0 & 1 \end{pmatrix}, \tag{A1}
\]

\[
e^{\mathcal{L}_V} = B(t) = \begin{pmatrix} 1 & 0 \\ -\tau & 1 \end{pmatrix}, \tag{A2}
\]

respectively, which act on the vector \( \Gamma \), and where \( \tau = \omega t \). For the one-step propagator, one thus finds from Eq. (23),

\[
e^{\mathcal{L}_{t/M}} \equiv B \left( \frac{\eta}{M} \right) A \left( \frac{t}{2M} \right) B \left( \frac{(1-2\eta)t}{M} \right) A \left( \frac{t}{2M} \right) B \left( \frac{\eta}{M} \right) = \begin{pmatrix} 1 - \frac{\tau^2}{2M^2} + \frac{\eta(1-2\eta)\tau^4}{4M^4} & -\frac{\tau - \frac{(1-2\eta)\tau^3}{4M^3}}{M} \\ -\frac{\tau + \frac{(1-2\eta)\tau^3}{4M^3}}{M^3} & 1 - \frac{\tau^2}{2M^2} + \frac{\eta(1-2\eta)\tau^4}{4M^4} \end{pmatrix}, \tag{A3}
\]

We will denote this approximate propagator matrix by \( P(t/M) \). The approximate propagator \( P(t) \) over a time \( t \) is given by the \( M \)-th power of \( P(t/M) \), which can be evaluated by diagonalization as follows:

\[
P \left( \frac{t}{M} \right) = U \text{ diag}(\mu_1, \mu_2) U^{-1}, \tag{A4}
\]

with \( \mu_1 \) and \( \mu_2 \) the eigenvalues of \( P(t/M) \), so that

\[
P(t) = U \text{ diag}(\mu_1^M, \mu_2^M) U^{-1}. \tag{A5}
\]

Because we want to minimize the error in front of the leading correction term, we only need the expansions of the eigenvalues and of \( U \) in inverse powers of \( M \). The eigenvalues may be expressed as

\[
\mu_1 = 1 + \frac{i\tau}{M} - \frac{\tau^2}{2M^2} - \frac{i(1+2\eta-4\eta^2)\tau^3}{8M^3} + O \left( \frac{1}{M^4} \right),
\]

\[
\mu_2 = 1 - \frac{i\tau}{M} - \frac{\tau^2}{2M^2} + \frac{i(1+2\eta-4\eta^2)\tau^3}{8M^3} + O \left( \frac{1}{M^4} \right),
\]

whence

\[
\mu_1^M = e^{i\tau} \left[ 1 + \frac{i(1-6\eta+12\eta^2)\tau^3}{M^3} + O \left( \frac{1}{M^4} \right) \right],
\]

\[
\mu_2^M = e^{-i\tau} \left[ 1 - \frac{i(1-6\eta+12\eta^2)\tau^3}{M^3} + O \left( \frac{1}{M^4} \right) \right],
\]

while the matrix \( U \) can be written as

\[
U = \begin{pmatrix} -i + \frac{i(1-6\eta+4\eta^2)\tau^2}{8M^2} & -i - \frac{i(1-6\eta+4\eta^2)\tau^2}{8M^2} \\ 1 & 1 \end{pmatrix} + O \left( \frac{1}{M^3} \right).
\]

Substituting these expressions into Eq. (A5), the deviations in the total energy from its initial value as a function of the initial conditions \( x_0 \) and \( p_0 \) can be written as

\[
E(t) - E(0) = \frac{1}{2} m \left| P(t) \Gamma_0 \right|^2 - \frac{1}{2} m \left| \Gamma_0 \right|^2 = \frac{1}{8M^2} \left( 1 - 6\eta + 4\eta^2 \right) \sin^2 \tau \left( m\omega^2 x_0^2 - p_0^2 \right) - 2\omega x_0 p_0 \cot \tau + O(M^{-3}). \tag{A6}
\]

Thus, the leading violation of energy conservation is of order \( 1/M^2 \) for general \( \eta \). In particular, the Verlet scheme, for which \( \eta = 1/4 \), has second-order violations in the energy conservation. Equation (A6) shows that the leading order violation can be eliminated altogether by taking the solution of \( 1 - 6\eta + 4\eta^2 = 0 \), i.e., \( \eta = (3 \pm \sqrt{5})/4 \). The larger of these solutions leads to negative time steps in the HOA2 scheme, which can lead to instabilities, so the value of \( \eta \) to take is \( \eta = (3 - \sqrt{5})/4 = 0.190 \ 983 \ 005 \ 625 \ 052 \ 6 \ldots \) This value of \( \eta \) makes the scheme pseudo-fourth-order for the harmonic oscillator, and is very close to the general optimized value of \( \eta = 0.193 \ 183 \ 327 \ 503 \ 783 \ 6 \ldots \) [28], which has been demonstrated to have smaller variations in the total energy than the Verlet scheme for general potentials in numerical simulations [15].

**APPENDIX B: FOURIER INVERSE FOR THE CLASSICAL WORK DISTRIBUTION**

To arrive at the classical result Eq. (64) for the finite-\( \tau \) switching process, one needs to compute
The integrand is a two-valued complex function with two singularities $-i\gamma_\pm$, which are also the branch points. The branch to take in the integral should be that for which the integrand is 1 at $u=0$ [since $G_\nu(0)=\int dW e^{iW}(W)=1$]. In addition, no branch cut should be crossed as one integrates from $-\infty$ to $+\infty$, i.e., the branch cut should not cross the real axis. This restricts the choice of where to put the branch cut: if $\gamma_+$ and $\gamma_-$ are of opposite sign, with $\gamma_+>0$ say, then in order to avoid a branch cut on the real axis the branch cut should have two parts, one extending from $-i\gamma_+$ to $-i\infty$ and one from $i\gamma_- \to i\infty$, as in the left panel of Fig. 6. If, on the other hand, $\gamma_+$ and $\gamma_-$ are both positive, then the branch points $-i\gamma_\pm$ both lie on the negative imaginary axis, and it is convenient to put the branch cut between the two branch points, as indicated in the middle panel of Fig. 6, while if $\gamma_+$ and $\gamma_-$ are both negative, the situation is mirrored with respect to the real axis, as shown in the right panel of Fig. 6. This third case can also be treated by setting $W\rightarrow -W$ and $u\rightarrow -u$ in Eq. (B1), and therefore does not need to be treated separately.

For the first case, i.e., $\gamma_+$ and $\gamma_-$ of opposite sign, with $\gamma_+$ chosen negative, one can shift the integration line up or down without hitting the branch points, until the integration line passes straight through the middle of the two branch points. In the integral in Eq. (B1), this corresponds to a shift of the integration variable over $i(\gamma_+ + \gamma_-)/2$. Performing in addition a scaling, such that $u=\gamma_-/2$, gives

$$P_0(W) = \frac{\sqrt{\gamma_+\gamma_-}}{2\pi} e^{-(\gamma_+ + \gamma_-)/2} W e^{-(i(\gamma_+ + \gamma_-)/2)W} \int_{-\infty}^{i\gamma_-} dt \frac{e^{-[(i(\gamma_+ + \gamma_-)/2)W]}}{\sqrt{1 + t^2}}$$

$$= \frac{\sqrt{\gamma_+\gamma_-}}{\pi} e^{-(\gamma_+ + \gamma_-)/2} W K_0\left(\frac{(\gamma_+ - \gamma_-)W}{2}\right)$$

using formula 8.432.5 in Gradshteyn and Ryzhik with $\nu=0$ and $z=1$ [29]. This result was also found by Deffner and Lutz [Eq. (27) in Ref. [25]] when they considered the classical limit of a real quantum dynamical process. However, $\gamma_+$ and $\gamma_-$ can only have opposite signs if the oscillator frequency is changed nonmonotonically, which is not the case considered in the text.

If $\gamma_+$ and $\gamma_-$ are both positive, which occurs for monotonically increasing oscillator frequencies [cf. Eq. (53)], one cannot simply shift the integration line to run in between the branch points since one of the branch points would be crossed. The integral is then evaluated as follows. For $W <0$, one can construct a contour $C_1$ composed of the real axis and an infinite semicircle in the upper half of the complex plane, as shown in Fig. 6. Because for $W<0$, the factor $e^{-iuW}$ decays exponentially when $u$ has a large positive imaginary component, the semicircle does not contribute to the integral, and the contour integral over $C_1$ has the same value as the original integral. Since no singularities lie within this contour, the integral is zero, proving that for $W<0$, the integral is zero. If, on the other hand, $W$ is positive, then the integrand decays for $u$ with a large negative imaginary component, and the integral can be replaced by an integration over the closed contour $C_2$ found by adding an infinite semicircle in the lower half of the complex plane, cf. Fig. 6. Note that because of the location of the branch cut, one remains on the same branch of the function going along $C_2$, which is a requirement for the contour to be truly closed. The contour $C_2$ does contain singularities, and in particular, it contains the branch cut. The contour can be deformed without crossing singularities to the contour $C_3$ in Fig. 6 which goes around the branch cut. One easily shows that the contributions from the parts that go around the branch points vanish. Furthermore, the integrand changes sign across the branch cut and the contour is traversed in opposite directions on either side, so that the contributions from the left and the right segments of $C_3$ are equal, and the integral becomes

$$P_0(W) = \int_{-i\gamma_-}^{i\gamma_+} \frac{du}{\pi\sqrt{1-\nu^2}} e^{-iuW}$$

Changing integration variables to $t$, where $u=[-(\gamma_+ + \gamma_-) + it(\gamma_+ - \gamma_-)]/2$ reduces this integral to

$$P_0(W) = \frac{\sqrt{\gamma_+\gamma_-}}{\pi} e^{-(\gamma_+ + \gamma_-)/2} W \int_{-\infty}^{\infty} \frac{dt e^{-(i(\gamma_+ - \gamma_-)/2)W}}{\sqrt{1 - t^2}}.$$
