Significance of the Study

• Hashimoto encephalopathy was diagnosed in a previously healthy 56-year-old female who presented with progressive cognitive decline and visual hallucinations. Extensive laboratory and diagnostic workup was done over the course of a 15-day hospitalization. The clinical picture of this patient illustrates the importance of awareness for Hashimoto encephalopathy, one of the few easily treatable causes of cognitive decline.

Hashimoto encephalopathy · Autoimmune thyroiditis · Steroid-responsive encephalopathy

Abstract

Objective: To present a case of Hashimoto encephalopathy as a complication of autoimmune thyroiditis. Clinical Presentation and Intervention: A previously healthy 56-year-old female presented with rapidly progressive cognitive decline and visual hallucinations. Being a diagnosis of exclusion, Hashimoto encephalopathy required an extensive laboratory and diagnostic workup, which was done over the course of a 15-day hospitalization. The patient recovered after initial treatment with intravenous methylprednisolone and was then switched to prednisone p.o. Conclusion: This case report illustrates the importance of awareness for Hashimoto encephalopathy, as it remains one of the few easily treatable and reversible causes of rapid cognitive decline.

Introduction

Encephalopathy is a broad diagnosis which can be caused by many different pathologic processes [1]. When creating a differential diagnosis for a patient with altered mental status and encephalopathy, a wide net must be cast to narrow down the possible causes. Common etiologies for encephalopathy may include but are not limited to uremic, hypertensive, hepatic, metabolic, infectious, paraneoplastic, and autoimmune etiologies among others. One very rare cause of acute encephalopathy is Hashimoto encephalopathy as a complication of autoimmune thyroiditis [2]. Patients presenting with neurologic changes consistent with encephalopathy must be further classified as either acute, chronic, or acute and chronic in order to facilitate a list of differential diagnoses. A syndrome of delirium and/or rapidly progressive dementia can help narrow the list of potential diagnoses, with Hashimoto encephalopathy being one potential cause. The diagnosis of Hashimoto encephalopathy is made as a diagnosis of exclusion, requiring the ruling out of many other potential causes [3].
Case Report

A 56-year-old female was brought to the emergency department with rapidly progressive cognitive decline and visual hallucinations over the course of the previous 3 weeks. Her past medical history was pertinent only for anxiety, migraines, and gastroesophageal reflux disease. The patient’s family history included multiple cerebral vascular accidents, epilepsy, thyroid disease, non-insulin dependent type 2 diabetes mellitus, and colon cancer. Her past surgical history included liposuction, bilateral gluteal fat implants, abdominoplasty, and bilateral breast reduction/breast lift. The patient had never before experienced any episodes of cognitive decline or hallucinations. On physical exam, the patient appeared drowsy and lethargic but was able to be aroused with pain stimulus and loud noise. She was unable to follow most commands, with the opening of mouth and sticking out of tongue being the only commands that were followed. The patient was not oriented to person, place, or time. Examination of the abdomen, chest, and extremities was not possible due to the patient’s unresponsiveness. Heart auscultation revealed regular rate and rhythm with S1 and S2 present. The lungs were clear to auscultation bilaterally in both upper and lower airways. Laboratory workup included: Hgb 11.7 g/dL, HCT 35.1 g/dL, glucose 102 mmol/L, sodium 140 mmol/L, potassium 3.8 mmol/L, calcium 9.5 mg/dL, creatinine 1.0 mg/dL, chloride 106 mg/dL, BUN 15 mg/dL, bilirubin total 0.53 mg/dL, bilirubin direct 0.2 mg/dL, TSH 1.79 μIU/L (range: 0.450–4.500), free T4 0.99 ng/dL (range: 0.8–1.8), and vitamin B12 520 pg/mL (range: 200–1,100). Ethanol <10.0 mg/dL, amphetamines, barbiturates, benzodiazepines, cocaine, opiates, phencyclidine, and tetrahydrocannabinol were all negative.

Upon arrival at the emergency department, the patient was taken for a CT-STAT of the head and brain which showed no verifiable acute intracranial abnormalities. Then, she underwent a chest X-ray which showed no radiographic evidence of acute cardiopulmonary disease. CBC, BMP, urinalysis, and urine drug screen were then ordered which showed no acute abnormalities (Table 1). The neurology and psychiatry departments were consulted, and the patient was admitted to the step-down unit. Due to the acuity of the presenting symptoms, the patient was examined for subacute encephalopathy versus rapidly progressive encephalopathy. MRI of the brain (without contrast), standard EEG, thyroid antibody panel, vitamin B12 level, and rapid plasma reagin (RPR) were all ordered on day 2 of hospitalization.

On day 3, the patient reported visual hallucinations and was oriented to person and time but not place. She was immediately started on levetiracetam, Haldol, and lorazepam for acute psychosis. Standard EEG results on day 3 showed bilateral temporal neuronal dysfunction (left > right) with the absence of seizure-like activity. Due to the epileptogenic potential of the standard EEG findings, a 24-hour EEG was then ordered to assess for epilepsy. On day 4, the patient remained oriented to person and time but not place with significant agitation. The results of the MRI of the brain (without contrast) showed several lesions within the supratentorial white matter, which were bright on DWI sequences with an area of cortical enhancement in the right occipital lobe and a periventricular lesion extending into the corpus callosum. This was of concern due to infarcts of a possible embolic etiology which prompted a cardiology consult.

On day 5, the patient remained oriented to person and time but not place with significant agitation. Lumbar puncture results (Table 2) showed no oligoclonal bands (ruling out multiple sclerosis),

| Parameters                              | Observed values | Reference range       |
|-----------------------------------------|-----------------|-----------------------|
| Hemoglobin                              | 11.7 g/dL       | 12–16 g/dL            |
| Leukocyte count                         | 8,600 cells/μL  | 4,500–10,000 cells/μL |
| Glucose                                 | 102 mmol/L      | 70–100 mg/dL          |
| Sodium                                  | 140 mEq/L       | 135–145 mEq/L         |
| Potassium                               | 3.8 mEq/L       | 3.5–5.0 mEq/L         |
| Calcium                                 | 9.5 mg/dL       | 8.5–10.2 mg/dL        |
| Creatinine                              | 1.0 mg/dL       | 0.5–1.1 mg/dL         |
| Chloride                                | 106 mg/dL       | 96–106 mEq/L          |
| Blood urea nitrogen                     | 15 mg/dL        | 7–20 mg/dL            |
| Total bilirubin                         | 0.53 mg/dL      | 0.1–1.2 mg/dL         |
| Direct bilirubin                        | 0.2 mg/dL       | <0.3 mg/dL            |
| Thyroid-stimulating hormone             | 1.79 μU/L       | 2.3–4.0 μU/L          |
| Free thyroxine (T4)                     | 0.99 ng/dL      | 1.0–2.0 ng/dL         |
| Vitamin B12 level                       | 520 pg/mL       | 200–1,100 pg/mL       |
| Serum West Nile virus IgG               | negative        | –                     |
| Serum West Nile virus IgM               | negative        | –                     |
| Urine drug screen (amphetamines, barbiturates, benzodiazepines, cocaine, opiates, phencyclidine, and tetrahydrocannabinol) | negative | – |
| Ethanol level                           | <10.0 mg/dL     | <10.0 mg/dL           |

Table 1. Laboratory data of the patient
IgG 9.9 mg/dL (normal 0.0–8.1), protein 126 mg/dL (normal 15–45), positive anti-treponemal Ab, negative RPR, and negative West Nile virus IgG and IgM. Serum West Nile virus IgG and IgM were also negative. Thyroid peroxidase Ab (TPO Ab) and thyroglobulin Ab showed TPO Ab 175 IU/mL (normal < 35) and thyroglobulin Ab 121.1 IU/mL (normal < 20). Due to the combination of cerebral spinal fluid (CSF) changes and thyroid antibody panel results, intravenous methylprednisolone 1,000 mg/day was started. Venereal Disease Research Laboratory test (VDRL) was also ordered to rule out possible neurosyphilis.

On day 6, the patient remained oriented to person and time but not place with significant agitation. Autoimmune workup was initiated and C3, C4, ACE, ANA, dsDNA, RF, atypical pANCA, C-ANCA, anti-SSA, and anti-SSB levels were all negative (Table 3). CTs of the chest, abdomen, and pelvis were obtained to rule out paraneoplastic etiology. The results of all CT scans were negative for neoplastic changes. An ultrasound of the bilateral carotid arteries was performed, which showed no stenosis. Intravenous methylprednisolone 1,000 mg/day was continued. On day 7, the patient remained oriented to person and time but not place with significant agitation. PCR of the serum definitively ruled out HSV-1 and -2 as a cause of encephalopathy (HSV encephalitis). Intravenous methylprednisolone 1,000 mg/day was continued.

On day 8, the patient remained oriented to person and time but not place. Her agitation had decreased. Due to underlying microcytic anemia and a remaining lack of definitive diagnosis, the patient was taken for colonoscopy to rule out a gastrointestinal lesion that could account for the anemia, as well as to rule out a potential gastrointestinal metastatic cause of the continued altered mental status. Colonoscopy showed a 3-mm tubular adenoma, which was removed; it was negative for malignancy. Transesophageal echocardiogram on day 8 showed ejection fraction >60%, the absence of wall motion abnormalities, and the absence of valvular disease. These results ruled out a cardioembolic cause of encephalopathy. Intravenous methylprednisolone 1,000 mg/day was continued through days 8 to 10. On days 9 and 10, the patient remained oriented to person and time but not place with continued lessening of her agitation. The patient was also becoming visibly more active.

Table 2. CSF analysis

| Parameters                          | Observed values | Reference range |
|-------------------------------------|----------------|-----------------|
| Oligoclonal bands                   | none seen       | –               |
| IgG antibody level                  | 9.9 mg/dL       | 0.0–8.1 mg/dL   |
| Protein level                       | 126 mg/dL       | 15–45 mg/dL     |
| Antithyroglobulin antibody          | 121.1 IU/mL     | <20 IU/mL       |
| Antithyroid peroxidase              | 175 IU/mL       | <35 IU/mL       |
| Anti-treponemal antibody            | positive        | –               |
| RPR                                 | negative        | –               |
| West Nile virus IgG                 | negative        | –               |
| West Nile virus IgM                 | negative        | –               |
| VDRL test                           | non-reactive    | –               |
| Toxoplasma antibody                 | negative        | –               |
| Acid-fast bacilli                   | negative        | –               |
| CSF culture                         | no growth       | –               |
| CSF pathology                       | no malignant cells seen | – |
| CSF flow cytometry                  | negative        | –               |

Table 3. Autoimmune panel

| Parameters                                      | Observed values | Reference range |
|-------------------------------------------------|-----------------|-----------------|
| C3                                              | 119 mg/dL       | 88–206 mg/dL    |
| C4                                              | 26.5 mg/dL      | 13–75 mg/dL     |
| Angiotensin-converting enzyme level*            | 36 U/L          | 8–53 U/L        |
| Anti-double stranded DNA                        | negative        | <30.0 IU/mL     |
| Rheumatoid factor level                         | negative        | <20.0 U         |
| Perinuclear antineutrophil cytoplasmic antibodies | <1.2 titer     | –               |
| Cytoplasmic antineutrophil cytoplasmic antibodies | <1.2 titer     | –               |
| Anti-Sjögren’s syndrome-related antigen A level  | <0.20 U         | <1.0 U          |
| Anti-Sjögren’s syndrome-related antigen B level  | <0.20 U         | <1.0 U          |

* Angiotensin-converting enzyme gene polymorphism.
On day 11, the patient was able to respond well to both voice and commands and was oriented to person, time, and place. MRA of the brain was obtained which was unremarkable, ruling out further vascular etiologies of altered mental status. At this time, the patient was transitioned from intravenous methylprednisolone 1,000 mg/day to prednisone 60 mg/day p.o. On day 12, the patient was oriented to person, time, and place and was very responsive. There was no agitation. CSF culture results and CSF acid-fast bacilli results were negative. CSF flow cytometry results were obtained on day 14 which was negative for lymphoproliferative processes. The patient remained on prednisone 60 mg/day p.o.

On day 15, the patient continued to improve. She was oriented to person, time and place, was awake and responsive and was able to ambulate on her own. After receiving negative results for both CSF VDRL and toxoplasma Ab IgM, the diagnosis of steroid-responsive encephalopathy (Hashimoto encephalopathy) as a complication of Hashimoto’s thyroiditis was made. The patient was discharged with prednisone 60 mg/day p.o. with outpatient follow-up scheduled within 1 week in the clinic.

Discussion

First described in 1966 by Brain et al., Hashimoto encephalopathy is a disease with no specific known cause and can occur even with normal thyroid function despite the presence of antithyroid antibodies. Once a potential diagnosis of Hashimoto encephalopathy is considered, conditions that must be ruled out include Creutzfeldt-Jakob disease, acute disseminated encephalomyelitis, toxic metabolic encephalopathies, meningoencephalitis, psychiatric disease, carcinomatous meningitis, paraneoplastic encephalitis, frontotemporal dementia, stroke/TIA, cerebrovascularitis, and basilar or hemiplegic migraine. Once all other etiologies are definitively ruled out, a diagnosis of Hashimoto encephalopathy can be considered [4].

In addition to ruling out all other etiologies, there are 3 essential features that must be present in order to diagnose Hashimoto encephalopathy: altered consciousness with reduced wakefulness, attention, or cognitive function, no CSF evidence of bacterial or viral infection; and high serum concentration (or titer) of antithyroid microsomal, antithyroid peroxidase, or antithyroglobulin antibodies [5]. To further support a diagnosis of Hashimoto encephalopathy, it is also essential that the patient has a profound improvement of mental status upon administration of a steroid treatment regimen. Because of this, Hashimoto encephalopathy has also been termed steroid-responsive encephalopathy [6]. Hashimoto encephalopathy has an estimated prevalence of 2.1 per 100,000 patients with unexplained neurologic symptoms, with a median age of 56 years and women being more affected than men [5]. In 2003, a 35-year national retrospective study showed that out of all patients in the United States who presented with noninfectious encephalopathy and a high serum antithyroid antibody concentration, only 105 patients were diagnosed with Hashimoto encephalopathy [7]. A total of 50% of patients presents with focal or diffuse nonenhancing MRI abnormalities during subacute exacerbation, and it can also be associated with nonspecific EEG abnormalities and elevated CSF proteins [8, 9].

Given the rarity of the condition, the exact dosage of steroids has not yet been established and there is no specific, accepted standard of care for the condition at this time. Daily oral prednisone (50–150 mg) as well as daily high-dose intravenous methylprednisolone have both been used, with the benefit of intravenous as compared to oral steroids being unknown. A total of 90–98% of patients with Hashimoto encephalopathy who are treated with steroids respond within weeks to months, with full recovery often achieved [10].

Conclusion

This case shows the importance of keeping a broad list of differential diagnoses to clinical practitioners when dealing with an encephalopathic patient, especially in the presence of antithyroid antibodies. It is essential for physicians to test for antithyroid antibodies in every case of acute encephalopathy as a means of ruling out or further exploring a diagnosis of Hashimoto encephalopathy. While it remains an extremely rare cause, it is also one of the few treatable and easily reversible causes of acute encephalopathy, making it much more important for the physician to recognize and treat.
