Oxygen-17 dynamic nuclear polarisation enhanced solid-state NMR spectroscopy at 18.8 T†

Nick J. Brownbill,a David Gajan,b Anne Lesage,b Lyndon Emsleyc and Frédéric Blanc*ad

We report 17O dynamic nuclear polarisation (DNP) enhanced solid-state NMR experiments at 18.8 T. Several formulations were investigated on the Mg(OH)2 compound. A signal enhancement factor of 17 could be obtained when the solid particles were incorporated into a glassy o-terphenyl matrix doped with BDPA using the Overhauser polarisation transfer scheme whilst the cross effect mechanism enabled by TEKPol yielded a slightly lower enhancement but more time efficient data acquisition.

Solid-state nuclear magnetic resonance (NMR) spectroscopy involving quadrupolar nuclei, which account for more than 75% of all active nuclei, has become an essential analytical technique for the atomic-scale characterization of a wide range of inorganic, hybrid and organic materials such as glasses, zeolites, surface catalysts, metal–organic frameworks, battery materials or pharmaceuticals to name but a few.1–4 While for spin \( I = \frac{1}{2} \) nuclei, the dipolar and chemical shift anisotropy (CSA) interactions are fully averaged out by magic angle spinning (MAS),5 producing sharp lines positioned at the isotropic chemical shifts, the second-order quadrupolar interaction observed for spin \( I > \frac{1}{2} \) is not fully removed by MAS,6–8 yielding field-dependent shifts and broadened NMR lines. These are some of the major limitations to the widespread applicability of quadrupolar NMR.7–10 The second-order quadrupolar broadening is inversely proportional to the strength of the external field \( B_0 \) and therefore very high magnetic fields allow high spectral resolution.11 In parallel, a range of NMR experiments have been designed to completely average out the second-order broadenings. They are based on technically challenging NMR probes permitting sample double rotation (DOR)12 or dynamic angle spinning (DAS),13 or consist of combining conventional MAS with the manipulation of the different nuclear spin transitions in techniques such as multiple quantum MAS (MQMAS)14 and satellite transition MAS (STMAS).15 Despite these sophisticated approaches and the increasing availability of high magnetic fields, the sensitivity of quadrupolar NMR remains often low for nuclei of poor natural abundance and/or of low gyromagnetic ratio \( \gamma_i \), requiring prohibitively long experimental times (days) and/or expensive isotopic enrichment.

A spectacular approach to increase the solid-state NMR sensitivity is dynamic nuclear polarisation (DNP),16,17 which involves the microwave-driven transfer of the large polarisation of unpaired electrons18–21 (e.g. added to the samples as paramagnetic polarising agents)22–28 to the surrounding nuclei in a glass-forming matrix at cryogenic temperatures, typically 100 K or below.29,30 The drastic signal enhancements permitted by DNP have opened up ground breaking applications on an ever increasing range of systems31–37 and the approach has been reviewed recently.38–42 Recent developments have extended the temperature range in which the experiments can be conducted (>200 K).43–45 One of the biggest drawbacks to MAS DNP under high magnetic fields results from the unfavorable evolution of the NMR signal enhancements with \( B_0 \), which scales as \( B_0^{-1} \) and \( B_0^{-2} \) for the two most common polarization transfer mechanisms, the cross effect (CE) and solid effect, respectively. However, large signal enhancements (>80) have recently been obtained at 18.8 T using the Overhauser effect (OE) DNP mechanism16,44,45 and the narrow-line 1,3-bis(diphenylene-2-phenylallyl) (BDPA) radical.46 The apparent linear scaling of the OE signal enhancement with \( B_0 \) currently represents one of the most attractive approaches for DNP under very high fields and is an exciting opportunity for quadrupolar nuclei.

A quadrupolar nucleus of particular interest is 17O due to the ubiquity of oxygen in materials chemistry and biochemistry. However, its extremely low natural abundance (0.037%) makes its NMR detection near impossible unless samples are 17O-enriched.47 The feasibility of MAS DNP on 17O has been recently reported.48–52 In particular, we demonstrated that high S/N natural abundance 17O cross polarization (CP) MAS NMR spectra could be obtained on...
nanoparticles, while more recently, the detection of $^{17}$O DNP NMR spectra of surface hydroxyl sites on mesoporous silica in natural abundance was reported. All these experiments were recorded at 9.4 T and relied on the CE mechanism with bTbk or TEKPol radicals in tetrachloroethane (TCE) as a polarising agent.

Here, we show that DNP can be applied to efficiently enhance the $^{17}$O MAS NMR signal of Mg(OH)$_2$ in a glassy matrix at 18.8 T, via both the CE and OE mechanisms. We show that CE DNP (using TEKPol/TCE) gives enhancements up to $\epsilon_{OCP} = 14$, and allows for the fast acquisition of the $^{17}$O spectrum of Mg(OH)$_2$ at natural abundance. Similarly, using the OE scheme, we demonstrate that polarisation can be transferred from BDPA in a glassy matrix (10% o-terphenyl (OTP), 90% o-terphenyl-d$_{14}$ (OTP-d$_{14}$)) to Mg(OH)$_2$ with excellent efficiency, giving enhancements of $\epsilon_{OCP} = 17$. Both CP and PRESTO-II (herein referred to as PRESTO) experiments are reported. Fig. 1a shows the 18.8 T DNP enhanced $^{17}$O MAS NMR spectrum of $^{17}$O enriched Mg(OH)$_2$ (i.e. Mg(17OH)$_2$), impregnated with TEKPol in TCE under the CE condition at $\nu_0(\mathrm{^1H}) = 800.130$ MHz. The $^1$H enhancement obtained on TCE ($N_H = 23$) is transferred to the protons of Mg(17OH)$_2$ via spin diffusion and subsequently to the $^{17}$O nuclei via a selective CP Hahn echo to yield a maximum signal enhancement of $\epsilon_{OCP} = 14$. In an attempt to be more representative in evaluating the increase in the NMR signal with DNP, we have estimated an overall DNP gain $\epsilon_{OCP}$ (see Section S2 of the ESI† for calculation details) to compare the benefit of 18.8 T DNP with standard NMR at 18.8 and 9.4 T. The $\epsilon_{OCP} = 14$ of TEKPol in a TCE matrix translates into a $\Sigma_{OCP}^{1}$ of 72 at 18.8 T (Table 1), demonstrating substantial CE DNP efficiency despite the $B_0^{-1}$ dependency of the CE. It is worth noting that on freshly prepared samples lower enhancements were observed ($\epsilon_{OCP} = 16$, $\epsilon_{OCP} = 9$) and that the maximum values reported above were obtained after holding the sample at 253 K for 20 h before freeze–thaw cycling (see the ESI†) and inserting it into the probe (Fig. 1 and Fig. S4, ESI†).

It was recently shown that the use of a PRESTO (phase-shifted recoupling effects a smooth transfer of order) sequence is more efficient for the $^1$H–$^{17}$O heteronuclear polarization transfer and yields for Mg(OH)$_2$, Ca(OH)$_2$ and silica surfaces line-shapes closer to simulations than with CP, including those in the context of MAS DNP. Fig. 1b shows the corresponding CE DNP $^{17}$O PRESTO

![Fig. 1](image-url) (a–d) $^{17}$O CE and (e and f) $^{17}$O OE MAS DNP at 18.8 T. CP (left column) and PRESTO (right column) spectra of Mg(17OH)$_2$ (a, b, c and d) and natural abundance Mg(OH)$_2$ (c and d) have been recorded at $\nu_0(\mathrm{^1H}) = 800.130$ MHz for the CE and at $\nu_0(\mathrm{^1H}) = 800.215$ MHz for the OE with microwave irradiation (w) at $\nu_0(\mathrm{^17O}) = 527$ GHz (green) at $T = 131$ K and without w (red) at $T = 115$ K. For the CE, both samples were impregnated with 16 mM TEKPol in TCE and paramagnetic O$_2$ removed by freeze–thaw cycles (see Section S1 in the ESI† for details). For the OE, the sample was prepared with a matrix containing 1.4 wt% BPDA in 90:10 OTP-d$_{14}$:OTP and five freeze–melt cycles (see the ESI†). Spectra (a and b), (c and d) and (e and f) are plotted in absolute intensity.

The $\mu$w off PRESTO spectrum of Mg(OH)$_2$ was not recorded. Asterisks (*) denote spinning sidebands.

Table 1 A comparison of DNP enhancements measured at 18.8 T using CP Hahn echo on Mg(17OH)$_2$ in a range of polarisation matrices (see the ESI†). n/a indicates that these experiments were not run.

| Matrix       | TCE       | OTP/OTP-d$_{14}$ (50:50) | OTP/OTP-d$_{14}$ (90:10) | OTP/OTP-d$_{14}$ (95:5) |
|--------------|-----------|--------------------------|--------------------------|--------------------------|
| Cross effect (1.3 wt% TEKPol) | $\epsilon_{OCP}$ | 14                        | 6                         | 12                         | 11                        |
| $\Sigma_{OCP}^{1}$ | 72        | 38                        | 54                        | 71                        | 53                        |
| Overhauser effect (1.4 wt% BDPA) | $\epsilon_{OCP}$ | 5                         | 2                         | n/a                       | 3                         |
| $\Sigma_{OCP}^{1}$ | 13        | 24                        | n/a                       | 34                        | 9                         |
spectra on the same Mg(17OH)2 sample at 18.8 T. A maximum signal enhancement of εPRESTO = 19 was obtained and is slightly higher than εCP (14). However, in our hands and at 18.8 T, the overall signal intensity is lower than with 17O CP as predicted.53 We also note that the asymmetric line shape and dephased spinning side bands are exacerbated by the addition of microwave irradiation (Fig. S3, ESI†). The lower intensity of PRESTO vs. CP and line shape disparity is also observed using the OE (Fig. 1e and f). The 17O signal enhancement factors obtained open the way to obtain natural abundance spectra using the CE at 18.8 T, and we were able to record 17O CP and PRESTO MAS NMR spectra of Mg(OH)2 relatively quickly in 82 minutes (Fig. 1c and d), while the corresponding microwave off spectra show no signal (Fig. 1c).

Sample formulation is essential to achieve high DNP enhancement factors, and in particular the choice of the solvent is often critical.54 It has been shown that OTP forms a highly effective glassy matrix and could be polarized by CE DNP with TEKPol and even more efficiently by OE DNP with BDPA.44,45,61 In the next paragraphs, we report 17O enhancement factors using OTP with both TEKPol and BDPA as the polarising matrix. The Mg(17OH)2 samples were prepared by grinding them with a mixture of protonated and fully deuterated OTP of various ratios containing TEKPol or BDPA radicals (1.3–1.4 wt% equivalent to 34 mM electron spins) followed by multiple cycles (typically 5) between a melt at ~343 K and a frozen state at 77 K (in liquid N2) before the melt was inserted into the precooled NMR probe at ~115 K (see the ESI† Section S1, for detailed sample preparation).

Fig. 2 plots the 13C and 17O CPMAS CE DNP signal enhancements of the Mg(17OH)2/TEKPol/OTP glass matrix as a function of the percentage of OTP-d14. The 13C and 17O enhancements correspond to the NMR signal amplification of, respectively, the OTP matrix and the Mg(17OH)2 particles. The data show that with a fully protonated OTP matrix, the signal enhancements are similar (εCP = 8 and εOCP = 6), revealing that the polarisation is efficiently transferred from the glassy matrix to Mg(17OH)2 and that the polarisation is evenly distributed across the particles by 1H–1H spin diffusion mechanisms.63 However, the enhancements are lower than with >50% OTP-d14 matrices (vide infra) and are due to both the large size of the 1H bath and the short 1H polarisation time τDNP (~3 s), yielding a fast decay of the enhanced polarisation by relaxation before it can be transferred to Mg(17OH)2. Increasing the content of OTP-d14 in the matrix improves the signal enhancements of the sample (Table 1 and Fig. S2, ESI†), in agreement with the previous literature showing that deuteration improves DNP enhancements,50,64 due to the decrease in 1H–1H spin diffusion and associated longer 1H τDNP (~31 s). This increase in enhancement plateaued by εOCP after 50% OTP-d14 and dropped off beyond 90% OTP-d14 in ΣεOCP, suggesting that for the CE with TEKPol/OTP at 18.8 T, a 90:10 mixture of OTP-d14 and OTP may be optimal for the signal to noise ratio per unit time per unit weight.

Fig. 2 also displays the 13C and 17O DNP signal enhancements under the OE condition of Mg(17OH)2 prepared in an OTP matrix (with various concentrations of OTP-d14) and using monoradical BDPA as a polarising agent, providing a comparison between CE and OE mechanisms at 18.8 T. At 90:10 OTP-d14:OTP, large matrix enhancements are observed (εH = 44, εOCP = 71), and subsequently the 17O enhancement of Mg(17OH)2 (εOCP = 17, Fig. 1e and 2) is substantially larger than with BDPA in a TCE matrix (εOCP = 5, Table 1 and Fig. S3, ESI†). The multiple freeze–melt cycles appear to improve the quality of the glassy matrix, and thus improve the enhancement values on the OTP matrix and sample, compared to directly inserting the sample into the probe (Fig. S5, ESI†). Contrary to the results observed under the CE condition with TEKPol, a further increase in OTP-d14 concentration to 95% yields a decrease in matrix enhancement factors (εH = 21, εOCP = 30), and very limited transfer of polarisation to the 17O of Mg(17OH)2.

Despite the maximum εOCP reported in Table 1 being for Mg(17OH)2/BDPA/90:10 OTP-d14:OTP, the corresponding 17O CP value is still lower than the maximum 17O CP values for 17O obtained with the CE (using the same matrix). This is due to the much shorter τDNP in the CE system (~11 s) than that of the OE in OTP-d14 (~31 s), allowing for more scans to be accumulated per unit time.

In conclusion, we have shown that it is possible to transfer the OE DNP enhanced polarisation of OTP doped with BDPA to the 17O spins of Mg(17OH)2 hydroxides at 18.8 T with good efficiency by mixing both solids together. We have also demonstrated that despite the lower ε values obtained with the CE, TEKPol/OTP and TEKPol/TCE provide time efficient signal enhancement. This has enabled a large gain in absolute sensitivity, permitting the challenging detection of natural abundance 17O NMR spectra. This study paves the way to a wider application of 15O DNP enhanced NMR under a high magnetic field and its transposition to other quadrupolar nuclei in a variety of crystalline and amorphous inorganic materials with strong second-order quadrupolar broadenings hampering the spectral resolution under a low field.
