ABSTRACT

Chandra high-resolution spectra toward eight low-mass Galactic binaries have been analyzed with a photoionization model that is capable of determining the physical state of the interstellar medium. Particular attention is given to the accuracy of the atomic data. Hydrogen column densities are derived with a broadband fit that takes into account pileup effects, and in general are in good agreement with previous results. The dominant features in the oxygen-edge region are O i and O ii Kα absorption lines whose simultaneous fits lead to average values of the ionization parameter of log ξ = −2.90 and oxygen abundance of Ao = 0.70. The latter is given relative to the standard by Grevesse & Sauvage, but rescaling with the revision by Asplund et al. would lead to an average abundance value fairly close to solar. The low average oxygen column density (N(O) = 9.2 × 10^{17} cm^{-2}) suggests a correlation with the low ionization parameters, the latter also being in evidence in the column density ratios N(O iii)/N(O i) and N(O iv)/N(O i) that are estimated to be less than 0.1. We do not find conclusive evidence for absorption by any other compound but atomic oxygen in our oxygen-edge region analysis.

Key words: atomic processes – ISM: abundances – ISM: atoms – X-rays: binaries – X-rays: ISM

1. INTRODUCTION

High-resolution X-ray spectroscopy provides a powerful technique for studying the interstellar medium (ISM) since the analysis of absorption features allows the identification of atomic and molecular transitions directly related to its physical and chemical properties. In this context, a chemical element of much interest is oxygen due to its cosmic abundance and foremost spectral features, namely K-edge structures whose models can lead to reliable estimates of its abundance, column densities, and ionization fractions.

A prominent oxygen K edge and hints of a resonant 1s → 2p absorption line were reported in the pioneering work by Schattenburg & Canizares (1986) on the Crab Nebula soft X-ray spectrum (<3 keV) taken with the Einstein Observatory. No apparent evidence for depletion was therein found thus implying dust grain sizes of <4 μm. A further attempt to exploit the oxygen K-shell absorption region was performed by Juett et al. (2004), who analyzed the spectra of seven X-ray binaries taken with the satellite-borne Chandra HETGS. Their model included two absorption edges (1s2s2p2p4P, 2P) and five Gaussians corresponding to Kα (1s → 2p) transitions in O i, O ii, and O iii and Kβ (1s → 3p) in O i. As a result, they managed to constrain the oxygen ionization fractions to N(O iii)/N(O i) ≈ 0.1 and N(O iii)/N(O i) ≲ 0.1. Yao & Wang (2005) performed a similar analysis including observations of seven Galactic low-mass X-ray binaries taken with both the High Energy Transmission Grating (HETG) and Low Energy Transmission Grating on board Chandra. The O vii and O viii Kα lines and the O vii Kβ detected in three of these sources were associated to the hot ISM whose distribution was also estimated; however, due to the few lines of sight, such inference could be biased. Costantini et al. (2005) studied high-resolution spectra of the Cygnus X-2 low-mass X-ray binary taken with the XMM-Newton space telescope, concluding that the complexity of the oxygen edge could be explained by absorption of both molecular and ionized atomic species. Moreover, in an analysis of the oxygen K-shell edge in XMM-Newton spectra toward galaxy clusters, Baumgartner & Mushotzky (2006) determined a high gas-to-dust ratio in the Galaxy, pointing out that the composition of denser clouds could be similar to the diffuse ISM.

Miller et al. (2009) have fitted Chandra HETG data from five X-ray binaries with an absorption model referred to as TBnew, and suggested that ISM absorption dominated the neutral column density. From similar observations of the line of sight of Cygnus X-2, Yao et al. (2009) detected K absorption lines from O i, O ii, O vi, O vii, and O viii, determining abundances that indicated mild oxygen depletion onto dust grains in the cold phase. From XMM-Newton Reflection Grating Spectrometer (RGS) spectra of the X-ray binary Sco X-1, de Vries & Costantini (2009) have deduced the presence of extended X-ray absorption fine structures and that around 30%–50% of the oxygen was bound in solid material. However, García et al. (2011) showed that, by using an accurate photoionization cross section for atomic O i, observations of this source in the 21.0–24.5 Å region could be adequately reproduced with no evidence of additional molecular and dust contributions. Pinto et al. (2010) have considered both the dust and gas components in the ISM absorption features toward the low-mass X-ray binary GS 1826–238; they found oxygen to be over abundant and a gas ionization degree above 5%, concluding that at least 10% of the oxygen was found in molecules or dust. More recently, Pinto et al. (2013) have measured oxygen column densities and estimated abundance gradients from XMM-Newton grating spectra of nine low-mass X-ray binaries,
concluding that 15%–25% of the oxygen is found in dust. They also point out that the ratios between different ionization stages are similar among the lines of sight suggesting large-scale chemical homogeneity. Liao et al. (2013) have analyzed 36 Chandra HETG observations from 11 low-mass X-ray binaries taking into consideration a correction for the Galactic rotation velocity relative to the rest frame. Through a Bayesian statistical approach and a combined fit, they detect several spectral features in the oxygen-edge region including Kα lines from O_i, O_ii, O_iii, O_iv, O_v, O_vi, and O_vii.

Gatuzz et al. (2013) have presented a self-consistent physical model of ISM oxygen K absorption to fit four Chandra spectra of XTE J1817−330, a low-mass X-ray binary with high signal-to-noise ratio. The oxygen K-edge region is fitted with a photoionization model derived with the xstar computer code (Bautista & Kallman 2001) referred to as war@abs. It is found that the K lines and photoionization cross sections must be slightly wavelength shifted in order to match the observed spectra. The resulting low ionization parameter indicate a dominant neutral component with absorption lines from O_i Kα, Kβ, and Kγ together with Kα from O_ii and O_iii. Kα lines from O_vi and O_vii are also detected, but it is argued that they probably arise in the neighborhood of the source rather than in the ISM; unsurprisingly, molecular features in the O K-edge region are not found in this study.

In the present work we refine the building blocks of our model of ISM oxygen photoabsorption, and explore its possibilities in describing the high-resolution Chandra spectra of eight X-ray binaries. Since this process is dominated by the neutral, we evaluate the impact of the atomic data on model prediction by considering both the new and definitive O_1 cross section by Gorczyca et al. (2013) and previous data of García et al. (2005). Although dramatic revelations are not expected with the present line-of-sight sampling, we are at least certain to contribute to the current discussion on ISM phase composition and local variability. The outline of the paper is as follows. In Section 2 we give details concerning the atomic data sets, and the observational reduction steps are described in Section 3. The fitting procedures of Gatuzz et al. (2013) for the broadband and oxygen-edge regions are recapitulated in Section 4 followed by the fit results (Sections 5 and 6). A discussion of results is carried out in Section 7 in order to draw some conclusions in Section 8.

2. ATOMIC DATA

A detailed and quantitative description of inner-shell photoabsorption processes is of vital importance to sustain astrophysical inferences from ISM X-ray absorption spectra, and as recently discussed for oxygen (Gorczyca et al. 2013), unsatisfactory discrepancies in both experimental and theoretical atomic data have led to a variety of disjoint conclusions regarding ionization and atomic-to-molecular fractions. In this respect, the spectral edge resonance structures, which give rise to useful astrophysical imprints, are particularly difficult to master as they strongly depend on ionization fractions and a variety of subtle relaxation effects such as Auger and radiative damping.

The latter atomic processes were taken into account in the photoabsorption cross sections of oxygen ions computed by García et al. (2005), which have been incorporated in the war@abs physical model (see Section 4). However, their previous application in X-ray binary spectral modeling, namely XMM-Newton and Chandra observations of Sco X-1 (García et al. 2011) and XTE J1817−330 (Gatuzz et al. 2013), required small wavelength shifts of the theoretical lines in order to secure accurate fits. Gorczyca et al. (2013) have recently made a serious attempt to establish a definitive photoabsorption model for O_i by taking care of all the relevant features—shoulder, line positions, widths, and oscillator strengths—and by providing a handy analytical expression for prospective users. However, a bothersome discrepancy of 0.6 eV still persists between the astronomically observed K-line position and laboratory measurements. Unconventionally and as fully discussed in Gorczyca et al. (2013), the final energy scale was calibrated by aligning to the former for the following reasons. First, the astronomical calibration is consistent with that of the well-understood O_vii Kα line. Second, the accuracy of the molecular data used in the experimental calibration is not altogether clear (Stolte et al. 1997; McLaughlin et al. 2013), and preliminary measurements appear to indicate that the experimental O_i K-edge calibration may indeed need a revision (W. C. Stolte 2014, private communications). Moreover, Gorczyca et al. (2013) also found a ∼10%–15% dispersion in the background photoionization cross sections that is now eliminated by benchmarking to the above-threshold experimental results (Henke et al. 1993). We are of the opinion that the small war@abs uncertainties due to these two cross sections finally close the argument on atomic oxygen data translation.

3. OBSERVATIONS AND DATA REDUCTION

In order to study the ISM oxygen edge along different lines of sight, we analyze Chandra spectra of eight low-mass X-ray binaries. Table 1 tabulates the observational specifications, namely IDs, dates, exposure times, and read modes. All spectra have been obtained with the medium energy gratings (MEGs) from the HETGS in combination with the Advanced CCD Imaging Spectrometer (ACIS). Observations were taken in continuous clocking mode or time exposure (TE) mode, in the former the temporal resolution is increased in order to minimize the pileup effect (Cackett et al. 2008). Pileup is concerned with the detection of two or more photons as a single event, and can produce a deformation of the continuum level and shape and, consequently, must be reduced as much as possible (Miller et al. 2006). We have estimated the pileup contribution along the broadband region with the simplegpipe2 procedure. In TE mode, the ACIS instrument reads the collected photons periodically. In both cases, we have reduced the data using the standard CIAO threads5 taking into account that, if the zero-order data were not telemetered, the zero-order position was estimated using the findzo algorithm.6 Finally, we have used the isis package (version 1.6.2–27)7 for spectral fitting.

4. FITTING PROCEDURE

Following Gatuzz et al. (2013), we estimate the hydrogen column density using an X-ray absorption model combined with a pileup convolution model (hereafter referred to as the broadband fit). We then reproduce the oxygen-edge region using the war@abs model to obtain physical properties related to the gas ionization and elemental abundances. In the broadband region (11–24 Å), we fit all observations for each source simultaneously with the simplegpipe2(TBnew(powerlaw)) model in order to obtain, using χ² statistics, an estimate of the

5 http://cxc.harvard.edu/ciao/threads/gspec.html
6 http://space.mit.edu/cxc/analysis/findzo/
7 http://space.mit.edu/cxc/isis/
hydrogen column density. The simplegpile2 is a convolution model that takes into account pileup effects, and TBnew is an X-ray absorption model that includes chemical elements with atomic numbers 1 \( \leq Z \leq 28 \) (see Gatuzz et al. 2013 for details). In addition to the H column density, \( N_H \), we treat the abundances of O, Ne, and Fe as free parameters. We group each spectrum to obtain a 0.1 Å bin size and add Gaussians to fit the remaining absorption lines, if any. We fix the absorption parameters in all observations, vary the power-law, pileup, and Gaussian parameters in each case. We then introduce the photoabsorption cross sections by Verner et al. (1996) and chemical abundances parameters in each case. We then introduce the photoabsorption cross sections by Garc´ıa et al. (2005) for O ions and (2) using the new cross section by Gorczyca et al. (2013) for O.

In the oxygen-edge region (21–24 Å), all sources display pileup effects, the broadband-fit parameters such as abundances and H column densities will be discussed in Section 5.1. In the oxygen-edge region (21–24 Å), we rebin the data to obtain 20 counts per channel in order to proceed with the analysis using TBnew output. Fit results are given in Table 2 including the set for XTE J1817–330 obtained by Gatuzz et al. (2013) where it may be seen that the reduced \( \chi^2 \) values denote a good fit in each case. Oxygen, neon, and iron abundances are found to be in the ranges 0.68 \( \leq A_O \leq 0.98 \), 0.51 \( \leq A_{Ne} \leq 1.62 \), and 0.56 \( \leq A_{Fe} \leq 1.21 \), respectively. For Sco X-1 we freeze the Ne abundance at the solar value because, as previously mentioned, its spectra do not include the Ne-edge absorption region (hydrogen column densities will be discussed in Section 5.1.). It should be noted that the TBnew model only accounts for photoabsorption cross sections of neutral species which, as discussed by Gatuzz et al. (2013), introduces a bias in the broadband-fit parameters such as abundances and H column densities. Regarding pileup effects, the simplegpile2.sl(TBnew(powerlaw)) model for each source in the 11–24 Å spectral region. In the case of Sco X-1 the fit was performed in the 15–24 Å interval as there are no counts below \( \sim 15 \) Å. For each source the observation with the highest signal-to-noise is plotted and residuals in units of \( \chi^2 \) are also given. In all cases the Ne-edge absorption region (13–15 Å) dominates the broadband fit due to a higher photon count (a factor of \( \sim 10 \) higher than the photon count in the oxygen edge).

5. BROADBAND FIT

Figure 1 shows the broadband fit using the simplegpile2.sl(TBnew(powerlaw)) model for each source in the 11–24 Å spectral region. The reduced \( \chi^2 \) values denote a good fit in each case. Oxygen, neon, and iron abundances are found to be in the ranges 0.68 \( \leq A_O \leq 0.98 \), 0.51 \( \leq A_{Ne} \leq 1.62 \), and 0.56 \( \leq A_{Fe} \leq 1.21 \), respectively. For Sco X-1 we freeze the Ne abundance at the solar value because, as previously mentioned, its spectra do not include the Ne-edge absorption region (hydrogen column densities will be discussed in Section 5.1.). It should be noted that the TBnew model only accounts for photoabsorption cross sections of neutral species which, as discussed by Gatuzz et al. (2013), introduces a bias in the broadband-fit parameters such as abundances and H column densities. Regarding pileup effects, the simplegpile2.sl model gives \( \beta \) values in the range 0.041 \( \leq \beta \leq 0.272 \) that correspond to pileup degrees in the 11–21 Å region lower than 68% for Sco X-1, 31% for Cygnus X-1, 17% for 4U 1820–30, and 6% for 4U 1636–53, 4U 1735–44, and GX 9+9.

In the oxygen-edge region (21–24 Å), all sources display pileup degrees lower than 1% that can be safely ignored although they must still be considered in the broadband-fit stage.
Figure 1. Best broadband fits with the $\text{TB}_{\text{new}}$ model of the spectra toward eight Galactic low-mass X-ray binaries. For each source the observation with highest signal-to-noise ratio is shown.
(A color version of this figure is available in the online journal.)

5.1. Hydrogen Column Densities

Hydrogen column densities derived in the broadband fit are compared in Table 3 with previous estimates, in particular two 21 cm surveys and the results by Juett et al. (2004) who obtained the continuum parameters from fits of the 23.7–24.7 Å line-free region. Good agreement is found except for Cygnus X-1 and Sco X-1. In the case of Cygnus X-1 it is important to note that, as discussed by Hanke et al. (2009), the 21 cm surveys do not resolve $N_\text{H}$ variations in the region around the source; therefore, we would consider our value to be more reliable. For Sco X-1 Bradshaw et al. (2003) found evidence for absorption as a function of X-ray branches (i.e., the position of the source in an X-ray color–color diagram), in a range from $N_\text{H} = (1.1 \pm 0.5) \times 10^{21}$ cm$^{-2}$ on the horizontal branch to $N_\text{H} = (32 \pm 5) \times 10^{21}$ cm$^{-2}$ on the normal branch. We conclude that, due to source variability, it is difficult to constrain the hydrogen column density; furthermore, it must also be pointed out that the discrepancies in $N_\text{H}$ estimates may also arise from the treatment of the source X-ray intrinsic continuum in each model.
Table 2

| Source          | TBlnew | SimpleGpile2\(\dagger\) | Reduced \(\chi^2\) |

6. OXYGEN-EDGE FIT

Figure 2 shows the best fits of the oxygen-edge region using the \texttt{warmabs(powerlaw)} model where, for each source, the observation with the highest signal-to-noise is plotted in the 21–24 Å wavelength interval. The dominant features are the O \(\text{I}\) and \(\text{O II}\) \textsc{K}\(\alpha\) absorption lines. Due to the low counts, the detection of absorption lines from resonances with principal quantum number \(n > 2\) is impaired, the exception being XTE J1817–330 with good quality spectra that also display \textsc{K}\(\alpha\) absorption lines from \(\text{O vi}\) and \(\text{O vii}\). In this respect, Gatuzz et al. (2013) have proposed that the \(\text{O vii}\) \textsc{K}\(\alpha\) line in XTE J1817–330 is formed in the source neighborhood rather than in the ISM. The puzzling absence of the latter line in other sources has been reported by Yao et al. (2009), who studied Cygnus X-2 spectra and suggested the possibility of an \(\text{O vii}\) resonance emission line annulling its absorption. This effect has been apparently confirmed by Cabot et al. (2013) in analyses of \textit{XMM-Newton} RGS and \textit{Chandra} MEG spectra, although the exact origin of the emission line is not completely understood.

The best \texttt{warmabs} fit parameters using the \(\text{O I}\) photoabsorption cross section by Gorczyca et al. (2013) are given in Table 4. For all sources the ionization parameter is found to be fairly low, with an average value of \(\log \xi = -2.90\) that points to the predominance of neutral and singly ionized oxygen species. There are differences in oxygen abundances among the lines of sight, \(0.33 \leq A_O \leq 1.34\), with an average value of \(A_O = 0.70\) that is consistent with the oxygen abundance reported for XTE J1817–330 by Gatuzz et al. (2013). If the \(\text{O I}\) photoabsorption cross section in \texttt{warmabs} is replaced with that by García et al. (2005), the outcome is not significantly different (see Table 5); an average ionization parameter of \(\log \xi = -2.92\), oxygen abundances in the range of \(0.54 \leq A_O \leq 1.02\), and an abundance average value of \(A_O = 0.68\). It must be clarified here, however,
that these O abundances are given relative to the solar standard by Grevesse & Sauval (1998), but as discussed by Gatuzz et al. (2013), if they are rescaled according to the revision by Asplund et al. (2009), the abundance average values would be fairly close to solar. The small differences in model output caused by the two photoabsorption cross sections give us confidence that the issue of oxygen atomic data accuracy has been finally settled, and consequently, the data set by Gorczyca et al. (2013) for O\textsubscript{i} can certainly be recommended as the standard in X-ray spectral modeling.

The oxygen gas abundances for 4U 1735–44 and GX 9+9 by Pinto et al. (2013) when rescaled to the solar standard of Grevesse & Sauval (1998), respectively \(A_O = 0.67 \pm 0.02\) and \(A_O = 0.71 \pm 0.02\), are in good agreement with the present values (see Table 4). On the other hand, for 4U 1820–30 we find \(A_O = 1.34 \pm 0.21\), a value greater than that estimated by Costantini et al. (2012) of \(A_O = 0.89 \pm 0.02\); however, the hydrogen column densities lead to a similar oxygen column density in both works.

For each source, Figure 3 shows the oxygen abundances obtained with the O\textsubscript{i} photoabsorption cross sections by both García et al. (2005) and Gorczyca et al. (2013). The sources are ordered according to their total counts (high to low), and the resulting abundance mean values are also shown. Since the abundances obtained for most sources with these two cross sections agree to within the error bars, we proceed our analysis

Figure 2. Best fits with the warmabs model of the oxygen-edge region in the spectra toward eight Galactic low-mass X-ray binaries. For each source the observation with highest signal-to-noise ratio is shown.

Notes. Fits carried out with the O i photoabsorption cross section by Gorczyca et al. (2013). Oxygen abundances relative to the solar value of Grevesse & Sauval (1998).

with the most recent (Gorczyca et al. 2013). The overabundance in the line of sight of 4U 1820−30 is worth noting since it could originate in the source neighborhood in the metal-rich NGC 6624 globular cluster (Güver et al. 2010), even though Costantini et al. (2012) have pointed out the difficulty of assigning the precise location of the absorbing gas. In a similar fashion, the ionization parameter for each source is depicted in Figure 4 where a low ionization degree is maintained along the different lines of sight. This result is consistent with the
predominant O i and O ii Kα absorption lines observed. Also, the scatter around the mean value is well constrained by the error bars that tend to increase with decreasing count number.

A map of the warmabs oxygen abundance versus ionization parameter is shown in Figure 5, where the error bars indicate that the ionization parameter is not as well constrained as the oxygen abundance; this is due to the saturation of the O i and O ii Kα lines. The plot shows that the ISM ionization state is generally low and the oxygen abundance lies below solar except for 4U 1820−30 where its overabundance, as previously mentioned, is likely to be due to its location in the metal-rich NGC 6624 globular cluster. The map of the warmabs hydrogen column density versus the warmabs oxygen abundance in Figure 6 shows that the hydrogen column density is better constrained, which may consequence of the low counts in the oxygen-edge region where the warmabs fits are performed. The high hydrogen column density of Cygnus X-1 has been attributed to the presence of an accreted stellar wind along the line of sight (Hanke et al. 2009).

6.1. Oxygen Column Densities

Total oxygen column densities (N_O = A_O N_H) are listed in Table 6 where the warmabs values take into account contributions from O i, O ii, and O iii. Data by Juett et al. (2004) are also tabulated, who estimated the oxygen column densities with the optical depth at 21.7 Å and the photoabsorption cross section by Gorczyca & McLaughlin (2000) at that wavelength. Cygnus X-1 has the highest oxygen column density probably due to the stellar wind from the supergiant companion star as discussed by Hanke et al. (2009). In the case of 4U 1820−30, its low hydrogen column density results in a low oxygen column density despite its high oxygen abundance.

A plot of the total oxygen column density versus ionization parameter is depicted in Figure 7. It shows that the sources appear to have both low ionization parameters and low oxygen column densities; if a correlation does exist between these two properties, a more extensive data analysis would be needed to verify it. For Cygnus X-1 and GX 9+9, the high hydrogen column densities increase the oxygen column densities although the sources have low ionization parameters. The average oxygen column density of our sampling is N_O = 9.2 × 10^{17} cm^{-2}.

7. ISM MULTIPHASE STRUCTURE

As signatures of a multiphase structure in the ISM, the presence of neutral, medium, and highly ionized atomic species

Figure 5. Map of oxygen abundance vs. ionization parameter denoting the low ionization state of the ISM. Oxygen abundances are mostly lower than solar relative to the standard by Grevesse & Sauval (1998) and close to solar relative to the revision by Asplund et al. (2009).

(A color version of this figure is available in the online journal.)

Figure 6. Map of the T_{\text{new}} hydrogen column density vs. warmabs oxygen abundance. The hydrogen column densities are better constrained than the oxygen abundances due to low counts in the oxygen-edge region.

in addition to molecules has been previously studied with high-resolution X-ray spectroscopy (Yao et al. 2009; Pinto et al. 2010, 2013; Costantini et al. 2012; Liao et al. 2013). They mostly involve the use of Gaussians to fit the observed absorption lines; for instance, Liao et al. (2013) have recently analyzed 36 Chandra HETG observations of 11 low-mass X-ray binaries by co-adding all the spectra. For each observation, the central wavelengths of the atomic transitions were corrected for the Galactic rotation velocity relative to the rest frame. Several transitions in the oxygen, magnesium, and neon edges were therein identified, followed by a Bayesian statistical analysis to determine the systematic uncertainties of the measurements. Very high accuracy is reached for the line positions, but in contrast to the present self-consistent model fit, the procedures based on Gaussians are limited regarding line identification and formation. A further disadvantage of such methods when compared to the simultaneous fit lies in the fact that the intrinsic lines with the higher signal-to-noise dominate the co-added spectra. This may lead to the wrong conclusion that each line is present in all observations; as a counterexample, we find that the O vi and O vii Kα absorption lines are only present in the XTE J1817−330 spectra as reported by Gatzu (Gatuzz et al. 2013).

It is known that the use of Gaussian profiles without an underlying analysis of the physical conditions of the gas can lead to incorrect identifications. For instance, Table 4 of Liao et al. (2013) lists Kα absorption lines from O iv and O v as well as O vi Kα, Kβ, and Kγ; however, as explained by Gatzu et al. (2013), the neutral component dominates such ISM spectra, and these lines would actually correspond to Kβ and Kγ transitions in O i and O ii. In support of this view, present results also point to the dominance of the ISM neutral component in different lines of sight, with a low ionization degree and small variations of the oxygen abundances due to plasma enrichment in the local environment (e.g., the presence of globular clusters). Table 7 lists the O i, O ii, and O iii column densities for each source as derived from a set of xstar simulations using the parameters from the warmab fit. In correspondence with the predicted low ionization parameters, the column density ratios N(O ii)/N(O i) and N(O iii)/N(O i) are estimated to be less than 0.1.

Contrary to Liao et al. (2013), we only detect O vi Kα in XTE J1817−330. As discussed in Gatzu et al. (2013), this line probably arises in the source neighborhood, and due to its brightness, an approach using multiple X-ray binaries and spectra addition is likely to assign its origin to the ISM; however,
our approach clearly confirms its absence in the rest of the sources. The appearance of highly ionized metal absorption lines in spectra toward Galactic X-ray binaries has been recently considered by Luo & Fang (2014), who found that most of them arise in the hot gas intrinsic to the source, the ISM only making a small contribution. On the other hand, UV studies have shown the presence of O vi lines toward multiple Galactic lines of sight that would enable us to determine the conditions required to detect O vi absorption in X-ray spectra. For example, Savage et al. (2003) and Sembach et al. (2003), using data from the Far-Ultraviolet Spectroscopic Explorer, derived O vi average column densities of 8.91 × 10^{13} cm^{-2} in the halo region, 2.39 × 10^{14} cm^{-2} in the Galactic thick disk, and 1.62 × 10^{14} cm^{-2} perpendicular to the Galactic plane. According to the atomic data used in this work, these values would correspond to equivalent widths (EWs) of 0.288 mÅ, 0.776 mÅ, and 0.512 mÅ, respectively. In this respect, we have performed data simulations using the HETG response files and typical exposure times that have led us to conclude that, for these EWs, a statistically acceptable detection would be unsuccessful. In fact, an O vi column density of at least 1.6 × 10^{15} cm^{-2} would be required to enable the fit of a Gaussian profile.

An inspection of our fit residuals, by no means negligible, has led to no conclusive evidence regarding photoabsorption by molecules or condensed matter. This may seem polemic as previous studies, even when using comprehensive physical models, have reported that some of the ISM oxygen is indeed depleted to the solid phase. For example, Pinto et al. (2013) have concluded that around 15%–25% of the oxygen is condensed by molecules or condensed matter. This may seem polemic, but fairly close to solar when rescaling to the revision of the standard for future X-ray spectroscopy.

We do not detect high-ionization lines except in XTE J1817−330 which, as mentioned by Gatzu et al. (2013), may arise in the source neighborhood rather than in the actual ISM. Using the O vi column densities obtained by Sembach et al. (2003) and Savage et al. (2003) from UV data, we have carried out a set of data simulations to estimate the typical column densities that would enable a statistically acceptable O vi Kα line detection, finding that a minimum of 1.6 × 10^{15} cm^{-2} is required to allow the fitting with a Gaussian.

Part of this work was carried out by Efraín Gatzu during a visit in 2014 January to the Laboratory of High Energy Astrophysics, NASA Goddard Space Flight Center, Greenbelt, Maryland, USA. Their hospitality and financial support are gratefully acknowledged. Manuel Bautista has received financial support from the National Science Foundation through grant AST-1313265. We would also like to thank Dr. Frits Paerels for comments at the refereeing stage that led to substantial improvements of the arguments presented and thus of the final quality of the paper.

8. CONCLUSIONS

We have carried out an analysis of ISM oxygen K absorption by means of high-resolution X-ray spectra toward eight low-mass Galactic binaries. For this purpose we are employing a physical model, referred to as warmabs, that is capable of determining the physical state of the gas. A broadband fit was performed to constrain the hydrogen column density using the simplegpile2.sl(TBnew(powerlaw)) model. The pileup effect was estimated from the fit indicating that it must be taken into account in the 11–24 Å region, although it can be safely ignored around the oxygen edge (21–24 Å). The hydrogen column densities derived from the fits are in good agreement with previous work, although in the case of Cygnus X-1 it is difficult to constrain it due to the presence of an alleged stellar wind along the line of sight.

For each source, the simultaneous fit of the oxygen-edge region with the warmabs model provides estimates of the ionization parameter and oxygen abundance. The simultaneous fit is implemented to avoid the overlapping between ISM and intrinsic absorption features thus allowing a reliable study through the line of sight. The low ionization degree is consistent with the prevalence of O i and O ii Kα absorption lines, supporting the dominance of the neutral component in the plasma. The fits yield an average oxygen abundance (A_O = 0.70) lower than solar if the standard by Grevesse & Sauval (1998) is assumed, but fairly close to solar when rescaling to the revision by Asplund et al. (2009). In the case of 4U 1820–30 oxygen enrichment is encountered, a likely consequence of the source location in the metal-rich NGC 6624 globular cluster. It is important to note that our conclusions are backed by the present benchmark of oxygen atomic data (Gorzyczka et al. 2013) which we now confidently recommend as the standard for future X-ray spectroscopy.
