ABSTRACT

Low pH, Al toxicity and low P often coexist and are heterogeneously distributed in acid soils. To date, the underlying mechanisms of crop adaptation to these multiple factors on acid soils remain poorly understood. In this study we found that P addition to acid soils could stimulate Al tolerance, especially for the P efficient genotype, HN89. Subsequent hydroponic studies demonstrated that solution pH, Al and P levels coordinately altered soybean root growth and malate exudation. Interestingly, HN89 released more malate under conditions mimicking acid soils (low pH, +P and +Al), suggesting that root malate exudation might be critical for soybean adaptation to both Al toxicity and P deficiency on acid soils. *GmALMT1*, a soybean malate transporter gene was cloned from the Al-treated root tips of HN89. Like root malate exudation, *GmALMT1* expression was also pH-dependent, being suppressed by low pH, but enhanced by Al plus P addition in roots of HN89. Quantitative real time PCR, transient expression of a GmALMT1-YFP chimera in Arabidopsis protoplasts, and electrophysiological analysis of Xenopus oocytes expressing GmALMT1 demonstrated that *GmALMT1* encodes a root-cell plasma membrane transporter that mediates malate efflux in an extracellular pH-dependent and Al-independent manner. Overexpression of *GmALMT1* in transgenic Arabidopsis, as well as overexpression and knockdown of *GmALMT1* in transgenic soybean hairy roots, indicated that GmALMT1-mediated root malate efflux does underlie soybean Al tolerance. Taken together, our results suggest that malate exudation is an important component of soybean adaptation to acid soils, and is coordinately regulated by three factors, pH, Al and P, through the regulation of *GmALMT1* expression and GmALMT1 function.
INTRODUCTION

Up to half of the world’s potentially arable lands are comprised of acid soils, which limit crop productivity in these regions (von Uexküll and Mutert, 1995). The stresses imposed on crops growing on acid soils consist of proton rhizotoxicity (low pH), nutrient deficiency (primarily phosphorus, but also potassium, calcium, and other minerals) and metal toxicity (aluminum, manganese). Among these constraints, low phosphorus (P) availability, toxic levels of aluminum (Al) and proton rhizotoxicity (low pH stress) are considered to be the three major stresses limiting plant growth on acid soils (Kochian et al., 2004).

The harmful effects of low pH for plants growing on acid soils could be direct or indirect. Low pH can directly inhibit root growth (Wilkinson and Duncan, 1989; Schubert et al., 1990; Kinraide, 1998; Koyama et al., 2001; Kinraide, 2003; Yang et al., 2005). Calcium may ameliorate inhibition of root growth by low pH through stabilizing the pectic polysaccharide network in the cell wall (Koyama, 2001). Changes in organic acid metabolism is another putative mechanism for plant adaptation to low pH stress, possibly via a cytoplasmic pH “stat” mechanism as was suggested in a study of the response of isolated wheat aleurone layers to low pH (Martinez-Camacho et al., 2004). Recently, the expression of the malate transporter gene that underlies Arabidopsis Al tolerance, AtALMT1 was found to be regulated in part by the transcription factor STOP1, which was identified via map-based cloning of an Arabidopsis mutant hypersensitive to low pH stress (Iuchi et al., 2007; Sawaki et al., 2009).

In acid soils, toxic forms of Al are released when the pH drops to 5 or lower. These active Al species, primarily Al$^{3+}$, can cause root damage and root growth inhibition by targeting the cell wall (Horst et al., 1999), the cytoskeleton (Sivaguru et al., 1999), callose production (Sivaguru et al., 2000), DNA (Yamaguchi et al., 1999; Meriga et al., 2004), the plasma membrane (Elstner et al., 1988) and disturbing stress-signaling pathways including regulation of cytosolic free Ca$^{2+}$ activities (Ramos-Díaz et al., 2007). Consequently, the inhibition of root growth and function on acid soils results in the severe impairment of water and nutrient acquisition by roots, leading to a significant reduction in crop yields (Ryan and Delhaize, 2001; Kochian et al., 2004). Over the past few decades, significant progress has been made in understanding the physiological and molecular mechanisms underlying Al tolerance in plants (Archambault et al., 1997; Degenhardt et al., 1998; Basu et al., 1999; Ma, 2000a; Sasaki et al., 2004; Huang et al., 2009; Yamaji et al., 2009; Huang et al., 2010). Aluminum activated root malate efflux is considered to be one of the major mechanisms for Al tolerance in a number of plant species, including wheat, Arabidopsis and Triticale.
Seminal work in this area came from Sasaki et al (2004) who identified the *TaALMT1* (or the Al-activated malate transporter) gene which encodes a membrane transporter mediating Al-activated root malate efflux in wheat root tips. Since this first study, *ALMT* genes involved in Al tolerance have been cloned and characterized in Arabidopsis (Hoekenga et al., 2006) and rape (*Brassica napus*) (Ligaba et al., 2006). It has been shown that overexpression of *ALMT* genes not only enhanced malate exudation but also improved Al tolerance in transgenic plants (Delhaize et al., 2009).

Phosphorus deficiency is another major soil constraint to agricultural production limiting crop yield in 30-40% of the arable lands in the world (Runge-Metzger, 1995). Plants have evolved a series of adaptive strategies such as the exudation of organic acids, in order to adapt to P deficiency in soils. Secreted organic anions mobilize P either by anion exchange or by chelating metal ions that form immobile complexes with P in the soil (Lipton et al., 1987; Vance et al., 2003). Plant species such as white lupin (*Lupinus albus*), buckwheat (*Fagopyrume sculentum*) and rape are quite efficient in mobilizing phosphate (Pi) from inorganic P complexes in the soil through enhanced malate exudation from roots (Hoffland et al., 1989; Hinsinger, 2001; Sas et al., 2001).

Since P deficiency and Al toxicity usually co-exist in acid soils (Kochian et al., 2004), the effects of P-Al interactions on plant adaptation to Al toxicity have been studied (Dong et al., 2004; Zheng et al., 2005; Liao et al., 2006; Jemo et al., 2007; Sun et al., 2008). Fukuda (2007) suggested a common metabolic system is responsive to both P deficiency and Al toxicity in rice. Tan and Keltjens (1990a, b) showed that P could ameliorate Al toxicity by improving root development and nutrient uptake in sorghum. Moreover, it has been suggested that immobilization of Al by P in the root cell wall is a potential mechanism for Al tolerance in buckwheat (Zheng et al., 2005), barley (*Hordeum vulgare*) (McCormick and Borden, 1972) and maize (*Zea mays*) (Gaume et al., 2001). Recently, organic acid exudation has been suggested to be involved in the P-dependent Al tolerance in plants. Ligaba et al (2004) showed that the P-sufficient rape accumulated and secreted more Al activated organic anions than the P-deficient plants. In our previous study, under Al stress in hydroponics, P application to shallow lateral roots in a divided root system was shown to stimulate malate exudation from the tap root tip of the P efficient soybean genotypes compared to the P inefficient genotypes, which also correlated with superior Al tolerance (Liao et al., 2006).

Although the mechanistic basis for P and Al interactions have been taken into consideration in a few studies on plant adaptation to acid soils, this subject is still quite
poorly understood, and the integration of $H^+$ and Al toxicity with P availability has not been addressed. Plants might adapt to low pH stress and Al toxicity through the same biological processes, as suggested by the identification of common $H^+$ and Al responsive genes in an Arabidopsis microarray analysis (Sawaki et al., 2009).

In the present study we first conducted a field trial to elucidate the responses of soybean growth of a P efficient and a P inefficient cultivar to heterogeneously distributed low pH, high Al and low P in acid soils. Subsequently, hydroponic experiments were carried out to analyze the coordinated regulation of root growth and root malate exudation by low pH, Al toxicity and differential P availability. Furthermore, a soybean homolog of the wheat $ALMT1$, $GmALMT1$, was isolated and characterized. The transcriptional regulation of $GmALMT1$ by low pH, Al toxicity and P availability was investigated. Transient expression of a GmALMT1-YFP chimera in Arabidopsis protoplasts and electrophysiological analysis in Xenopus oocytes expressing GmALMT1 demonstrated that $GmALMT1$ encodes a plasma membrane malate transporter. The $in planta$ role of GmALMT1 in root malate exudation and Al tolerance was demonstrated via overexpression in transgenic Arabidopsis plants, as well as overexpression and knockdown of $GmALMT1$ in transgenic soybean hairy roots.

RESULTS

Performance of Soybean in Acid Soils at Two P Levels

Soil pH, Al and P content were found to be heterogeneously distributed along vertical acid soil profiles in the field; thus these acid soils could be divided into three layers (Table S1). With increasing soil depth, the pH value and exchangeable P content significantly decreased, whereas the exchangeable Al content significantly increased. In the deepest soil layer (40-60 cm), exchangeable P was totally undetectable and the pH value had decreased to 4.29 (from pH 5.71 in the 0-20 cm soil layer), while the exchangeable Al content increased to 3.04 cmol.kg$^{-1}$, which was twice that measured in the top soil layer (0-20 cm).

A previous study from our lab showed that HN89 is a P-efficient genotype, while HN112 is a P-inefficient genotype (Zhao et al., 2004). Growth performance of these two soybean genotypes was investigated on acid soils at two P levels (Fig. 1). Without P application, total root length of HN89 (a P efficient genotype) and HN112 (a P inefficient genotype) were almost identical. With P fertilization to the topsoil resulted in a significant increase (about 42%) in total root length for the P-efficient genotype (HN89) in response to P application (Fig. 1A). In contrast, the total root length in the P inefficient genotype HN112 was relatively unaffected. Furthermore, total plant biomass was significantly higher in the P
efficient genotype HN89 relative to that of the P inefficient genotype HN112 at both P levels (Fig. 1B). Plant dry weight of HN89 was 100% and 75% greater than that of HN112 at low and high P levels, respectively. These findings suggested that the enhanced growth of the P efficient genotype upon supplying P might partially result from enhanced Al tolerance via improved root growth. This possibility was investigated further as detailed below.

**Interaction of Al, pH and P on Soybean Root Growth**

To elucidate plant responses to the interactions among Al, low pH and P, relative root growth was quantified in soybean plants grown in hydroponic culture under specific pH, Al and P conditions. Results showed that Al tolerance was influenced by P availability (Fig. 2). Under low P conditions, the relative root growth of both soybean genotypes was significantly inhibited by Al addition (52% and 49% inhibition in HN89 and HN112, respectively). Under +P conditions, the adverse effects of Al on relative root growth were ameliorated in both genotypes (Fig. 2), with the P efficient genotype HN89 exhibiting a significantly higher relative root growth than HN112 under this treatment (115% versus 90%). These results were consistent with the results from the field studies (Fig. 1A), indicating that the P efficient genotype HN89 was more Al tolerant, but only under conditions of P supply. However, the two genotypes showed no significant differences in relative root growth in response to low pH or P availability under –Al conditions (Fig. 2).

**Changes in Root Malate Content and Exudation in Response to pH, P and Al**

Root malate exudation and internal malate content of soybean root tips were found to be coordinately influenced by changes in pH, P and Al in the growth media (Fig. 3). In the higher pH nutrient solution (pH 5.8), malate exudation in the P efficient genotype HN89 was significantly higher than in the P inefficient genotype HN112, independent of the P treatment (Fig. 3A). Acidification (pH 4.3) of the nutrient solution resulted in a significant reduction in root malate exudation (70% and 55% in HN89 and HN112, respectively) under high P supply. Addition of Al to this high P/low pH nutrient solution increased malate exudation by 130% and 43% in NH89 and NH112, respectively. In contrast, the effects of media acidification and addition of Al were less pronounced under low P supply. Interestingly, under conditions mimicking acid soils (low pH, +P and +Al), roots of the P efficient genotype HN89 secreted more malate than those from the P inefficient genotype, HN112 (Fig. 3A). This result suggests that the role of root malate exudation is more than just a response to toxic Al in soybean roots on acid soils, such as that the enhanced malate exudation at low pH and low P availability might also be involved in plant-mediated release of Pi from insoluble P forms on acid soils.
Although the internal malate content in root tips from both genotypes also decreased significantly upon acidification on the growth media, root malate content was not affected by Al treatment (Fig. 3B). Furthermore, in contrast to the changes in malate exudation observed under high P and +/-Al, addition of P in the low pH solution resulted in an Al-independent and moderate increase in malate content in the root tips of both genotypes. Interestingly, the P efficient genotype HN89 maintained significantly higher root tip malate content than in the P inefficient genotype HN112 throughout most treatments (except high P and pH). Overall, these findings suggest that maintenance of malate synthesis/accumulation in root tips is significantly influenced by external pH and the P efficiency of plants.

Isolation of the Malate Transporter Gene, \textit{GmALMT1}, from Soybean

A 405 base pair (bp) \textit{GmALMT1} fragment was amplified from cDNA derived from soybean root tips of HN89 subjected to Al treatment using a pair of degenerate primers based on the conserved sequence motif from the Al-dependent malate transporters TaALMT1 (Sasaki et al., 2004), AtALMT1 (Hoekenga et al., 2006) and BnALMT1 (Ligaba et al., 2006). This fragment was used to obtain the corresponding full-length cDNA via RACE-PCR. The coding region of \textit{GmALMT1} (NCBI gene bank accession number: ACC60273) was 1461bp in length with the deduced protein consisting of 486 amino acid residues. Blast analysis indicated that GmALMT1 was 46% identical to AtALMT1 from Arabidopsis, 48% identical to BnALMT1 from rape, and 43% identical to BnALMT1 from wheat.

Phylogenetic analysis showed that soybean ALMT family member proteins and ALMTs with known functions in other plants species could be grouped into three clades (Fig. S1). AtALMT9 and AtALMT12 were grouped into clade I and clade II, respectively, while other ALMT1 proteins together with GmALMT1 were grouped into clade III. Interestingly, those ALMTs in clade III were further classified into two subgroups, the monocot group (i.e. ZmALMT1, TaALMT1 and HvALMT1) and the dicot group (i.e. GmALMT1, BnALMT1, BnALMT2 and AtALMT1) (Fig. S1).

\textit{GmALMT1} Expression is Regulated by pH and Al

Quantitative real time PCR (qRT-PCR) was used to analyze \textit{GmALMT1} expression patterns in soybean seedlings. As shown in Figure 4A, \textit{GmALMT1} expression was primarily localized to the root apex of tap roots (Fig. 4A). In the absence of Al-stress, a low expression level of \textit{GmALMT1} was observed in the root tips (first 0-2 cm of the root), being almost undetectable in the other root regions. However, after 6 h of Al\(^{3+}\) exposure, the level of \textit{GmALMT1} transcript abundance was increased by more than 3-fold in the root tips, while no significant changes of \textit{GmALMT1} expression were observed in the other root regions (Fig.
Expression of \textit{GmALMT1} in the root tip was Al-dependent, increasing with increasing Al levels (Fig. 4B). To determine whether \textit{GmALMT1} expression was affected by the interaction of pH and Al toxicity, temporal expression patterns of \textit{GmALMT1} were also examined in the root tips. As shown in Figure 4C, expression of \textit{GmALMT1} in the root tips was regulated both by pH and Al. The levels of \textit{GmALMT1} expression were high in the root tips of the seedlings grown in pH 5.8 nutrient solution prior to subjecting the seedling roots to low pH (Fig. 4C). The \textit{GmALMT1} expression decreased by more than 12-fold after 6 h of low pH treatment, remaining low over the next 6 hours. Inclusion of Al in the low pH solution resulted in a 2-fold increase of \textit{GmALMT1} transcript abundance within 2 h of Al exposure, increasing up to a 4-5 fold after 4-6 h of Al treatment. Thereafter, expression levels of \textit{GmALMT1} gradually decreased over the next 18 hrs of Al treatment (Fig. 4C). These results indicated that low pH strongly suppressed, while Al$^{3+}$ transiently enhanced the expression of \textit{GmALMT1}, with the enhancement of \textit{GmALMT1} expression by Al$^{3+}$ being greater than the suppression by low pH.

\textit{GmALMT1} Expression Appears to be Coordinately Regulated by P, pH and Al

As shown in Figure 5, the expression levels of \textit{GmALMT1} in soybean roots appeared to be coordinately regulated by pH, Al and P. The levels of \textit{GmALMT1} transcript abundance in both genotypes decreased at low pH, with this response being partly dependent on P availability (Fig. 5). In +P conditions, \textit{GmALMT1} expression under the higher pH conditions (pH 5.8) was approximately 3-fold higher than that measured under low pH conditions (pH 4.3), with no significant differences observed between genotypes. However, in -P media at pH 5.8, \textit{GmALMT1} expression in the P efficient genotype HN89 was significantly higher than in HN112 (P inefficient). When the -P growth solution pH was decreased to pH 4.3, there were only 20% and 40% decreases in \textit{GmALMT1} transcript abundance in HN89 and HN112, respectively, which were significantly smaller low pH induced decreases in expression compared to the reductions observed in the +P media (Fig. 5). These findings are in agreement with the root malate exudation data shown in Figure 3A, where lowering the pH in the +P growth solution resulted in a significant decrease in root malate exudation in both genotypes, consistent with the reduction in \textit{GmALMT1} expression levels seen in Figure 5. Further regression statistics analysis showed that the coefficiency ($R^2$) between malate exudation and \textit{GmALMT1} expression was 0.83 or 0.71 at high or low P level, respectively, which was significant at 0.05 level, suggesting that malate exudation is highly regulated by \textit{GmALMT1} expression. Likewise, and most relevant to the coordinate regulation of Al tolerance theme, inclusion of Al in the pH 4.3 treatment solution resulted in a significant
increase in root malate exudation predominantly in the P efficient genotype HN89 (Fig. 3A), and the same treatment resulted in a significant increase in GmALMT1 expression only in the P efficient genotype HN89, and only in response to +P treatment.

**GmALMT1 is a Plasma Membrane-localized Transport Protein Membrane**

Like other plant ALMTs, the GmALMT1 protein is predicted to harbor six membrane spanning domains in the protein using hydropathy plot analysis (PSORT: http://psort.ngc.jp/form.html) (data not shown). The cellular localization of GmALMT1 was investigated by transiently expressing the YFP::GmALMT1 translational fusion in Arabidopsis leaf protoplasts (Fig. 6). In control protoplasts (transformed with the empty vector), fluorescence associated with the soluble YFP was observed throughout the cytosol. In contrast, in protoplasts transformed with YFP::GmALMT1, the fluorescence was localized predominantly to the cell periphery, suggesting a plasma membrane localization. This was confirmed by the co-localization of the fluorescence from the YFP::GmALMT1 protein with the fluorescence associated with the plasma membrane-specific fluorescent dye (Fig. 6: Third column).

**GmALMT1 Encodes a Membrane Transporter that Mediates Malate Efflux**

Functional characterization of GmALMT1 was carried out by heterologously expressing the gene in *Xenopus laevis* cells and examining their electrophysiological properties. Oocytes injected with GmALMT1 cRNA had significantly less negative resting membrane potentials (RMP) than control cells in standard solutions at both pH 7.5 and 4.5 (Fig. 7A), suggesting that expression of GmALMT1 resulted in a reduction of the net internal negative charge (relative to that found in control cells) as a result of net anion influx or net cation efflux. Further characterization was performed using the conventional two-electrode voltage-clamp (TEVC) method (Fig. 7B and C). In standard bath solutions at pH 7.5, GmALMT1-expressing cells mediated large inward (i.e. negative) currents and smaller outward (i.e. positive) currents. Acidification of the bath media to pH 4.5 resulted in enhancement of the GmALMT1-mediated outward currents, while have no major effect on the GmALMT1-mediated inward currents. In contrast, under both sets of ionic conditions, control cells showed no significant currents within the range of holding potentials tested. Since, by convention GmALMT1-mediated inward currents are the product of either net positive charge influx or net negative charge efflux (which would be consistent with efflux of the malate anion), to further characterize the nature of the GmALMT1-mediated transport the intracellular malate activities ([mal\(^{-2}\)]\(_i\)) were increased from basal endogenous levels (zero) up to 4.5 mM via microinjection of malate using well characterized protocols (see, Piñeros et
al., 2008), thereby increasing the organic anion efflux driving force. Increasing \( \text{mal}^2- \) resulted in a concentration-dependent increase in the GmALMT1-mediated inward currents in standard bath solutions at both pH 7.5 and 4.5 (Fig. 8). In contrast, although being pH dependent (i.e. stimulated at lower pH as shown in Fig. 7), GmALMT1-mediated outward currents were independent of changes in \( \text{mal}^2- \). Under increased \( \text{mal}^2- \) conditions, we were also able to establish that acidification of the bath media resulted in inhibition of the GmALMT1-mediated inward (i.e. negative) currents at all \( \text{mal}^2- \) tested. Analysis of the slope of GmALMT1-mediated inward current (conductance) at pH 7.5 and 4.5 showed that the inward conductance tended to saturate as the \( \text{mal}^2- \) approach 4 mM, suggesting that the GmALMT1-mediated malate transport saturates with a \( K_{m1/2} \) of about 1 to 2 mM internal \( \text{mal}^2- \), independent of the extracellular pH value (Fig. 8C). These findings also suggest that decreasing the pH of the bath solution from pH 7.5 to 4.5 results in a change in the maximum conductance (\( G_{\text{max}} \)) rather than a change in affinity for the malate substrate. The dependence of the magnitude of the GmALMT1-mediated steady state inward currents on increasing \( \text{mal}^2- \) shown in Figure 8A-C was also accompanied by a positive shift in \( E_{\text{rev}} \) (the holding potential at which the current reverses sign) of about -15 mV as \( \text{mal}^2- \) was increased to 4.5 mM (data not shown). Comparison of the current to voltage relations generated by a voltage ramp protocol with GmALMT1-expressing cells confirmed that an increase in \( \text{mal}^2- \) resulted in a significant shift in \( E_{\text{rev}} \) towards more positive potentials (Fig. 8D). In contrast, control cells showed no significant shift in the reversal potential upon increasing \( \text{mal}^2- \). At low pH values, the transport activity of GmALMT1 was independent of the presence or absence of \( \text{Al}^{3+} \) (100 \( \mu \text{M AlCl}_3 \)) in the bath media (data not shown). Overall, the increase in inward current upon increasing \( \text{mal}^2- \) and the concomitant positive shift in \( E_{\text{revs}} \) are consistent with GmALMT1-mediated inward currents being the product of anion efflux, ultimately indicating that at physiologically relevant membrane potentials, GmALMT1 functions as a transporter capable of mediating malate efflux from the cell. Furthermore, the pH dependence of the transporter (i.e. lower transport rates at lower pH) suggests that in addition to changes in gene expression, the pH dependence of the whole root malate exudation described above (i.e. Fig. 3A) is quite likely also the product of the functional characteristics of the GmALMT1 transporter mediating this process in planta in response to lowering the pH of the solution bathing the root.

**Overexpression of GmALMT1 in Transgenic Arabidopsis Plants Confers Al Tolerance**

The function of GmALMT1 was further investigated in two Arabidopsis transgenic lines (OX1 and OX2) overexpressing GmALMT1. Quantification of GmALMT1 transcript
abundance in the two transgenic lines by qRT-PCR indicated that *GmALMT1* was highly expressed in these transgenic but not in CK lines (Fig. 9A). These two overexpression lines showed significantly larger root malate exudation rates and superior Al-tolerance (as determined by relative root growth) compared to CK (Fig. 9B-D). These results clearly demonstrate that overexpression of *GmALMT1* in Arabidopsis promotes root malate release, thereby conferring a significant increase in Al tolerance.

**GmALMT1 Mediates Malate Exudation and Determines Al Tolerance in Soybean Transgenic Hairy Roots**

The role of GmALMT1 as a malate efflux transporter was further verified in transgenic soybean hairy roots overexpressing *GmALMT1* (GmALMT1-OX) and with reduced *GmALMT1* expression via RNA interference (GmALMT1-KD). The *GmALMT1* transcript abundance for these transgenic lines was confirmed via qRT-PCR (Fig. 10A). *GmALMT1* transcript abundance was 1.4 times higher in the GmALMT1-OX lines compared with the CK line, while the transcript levels in the GmALMT1-KD lines were 50% lower than those in the CK. As shown in Figure 10B, the malate exudation rates from the hairy roots of these lines was closely correlated with the level of *GmALMT1* expression, being 58% lower in the GmALMT1-KD lines and 87% greater in the GmALMT1-OX lines, relative to those measured in the CK. The function of GmALMT1 related to Al tolerance was also quantified in soybean transgenic hairy roots. As this hairy root system is not amendable to relative root growth measurements, root Al exclusion measured with the Al stain, hematoxylin, was used as a physiological measure of Al-tolerance. After 3 hours of exposure to 50 µM Al, the hairy roots of the GmALMT1-OX lines accumulated less Al in the root tips than CK roots, as indicated by the degree of hematoxylin staining on the surface of the root tips (Fig.10C).

Overall, these results strongly suggest that GmALMT1 does function as a malate efflux transporter in soybean roots, chelating free Al at the root surface and excluding it from entering the root system, thereby providing Al-tolerance.

**DISCUSSION**

Highly acidic soil pH, high Al and low P availability are the three major limiting factors in acid soils comprising up to 40% of world arable land and severely inhibit world crop production (Kochian et al., 2004). Although it has been reported that crops such as rice, maize and common bean have great genetic potentials for adaptation to acid soils, most of the phenotypic screening in these types of studies have been conducted either in the field or performed in the lab and have focused primarily on Al tolerance or occasionally on P
efficiency (Cranados et al., 1992; Rao et al., 1993; Yan et al, 1995). Only a very few studies have simultaneously considered P availability and Al toxicity together (Zheng et al., 2005; Liao et al., 2006). Since soil pH, levels of rhizotoxic Al species and P availability are not homogeneously distributed in acid soils, it is clear that plant roots have to deal with different levels of low pH, Al toxicity and P availability during their growth through acidic soil horizons (Table S1; Liao et al., 2006). Therefore, the present study represents, to our knowledge, the first multidisciplinary study to focus on the combined effects of these three major limiting factors in acid soils to plant growth, implementing field evaluations and physiological, molecular and biophysical analysis in the lab, to elucidate the underlying mechanisms of crop adaptation to acid soils.

For crops to maintain growth on acid soils, they need to be adaptive to low pH (toxic levels of H+), Al toxicity and/or P deficiency (Kochian et al., 2004). Our field trials indicated that the P efficient soybean genotype adapted better to acid soil conditions than the P inefficient genotype, showing significantly greater biomass and longer total root length, especially under conditions of P supply (Fig. 1). Further studies in hydroponics also showed that the P efficient soybean genotype exhibited greater tolerance to Al when P was supplied (Fig. 2), consistent with our previous report indicating that P efficient soybean genotypes are more Al tolerant under P application (Liao et al., 2006). It should be noted here that the effect of P supply on enhancing Al tolerance was not simply due to the added Pi chelating Al$^{3+}$ in the nutrient solution. Careful design of the hydroponic nutrient solutions using the ion speciation program GEOCHEM-EZ (Shaff et al., 2010) guaranteed that there were identical levels of free Al$^{3+}$ activity in both +P and –P nutrient solution. Our findings lead us to suggest that greater adaptation to acid soils may in part the results of greater P efficiency, as well as greater tolerance to Al toxicity and low pH. The underlying mechanisms associated with the P efficient genotype only exhibiting better Al tolerance under conditions of sufficient P supply will be discussed later in this section.

Previously, we found that malate exudation from the tips of the more deeply growing tap root of the P efficient soybean genotype was specifically enhanced when the upper, more shallowly placed lateral roots, were supplied with P while the tap root tip was challenged by Al, suggesting that P efficiency resulting in improved P nutrition plays a role in the malate exudation critical for Al tolerance (Liao et al., 2006). This hypothesis is also supported by the results from studies in rape, where it was shown that root malate exudation was up-regulated by the interactions of P and Al (Ligaba et al., 2004). Furthermore, several studies have also suggested that malate exudation and internal malate homeostasis could play vital roles in
plant adaptation to low pH stress, Al toxicity or P deficiency (Hoffland et al., 1992; Martínez-Camacho et al., 2004; Sasaki et al., 2004). In the present study, we used a hydroponic system to analyze the relationships between malate exudation and internal malate homeostasis in response to changes in solution pH, and Al, and P levels in the growth solution. Our results indicate that in control solution (pH 5.8, +P, -Al), root malate exudation was much higher than in the same solution adjusted to pH 4.3 (Fig. 3A). Similar responses have also been observed in other plant species (Bertin et al., 2003). High root malate release has been speculated to be involved in other plant responses to the environment, such as in interactions between plants and soil microorganisms (Walker et al., 2003; Rudrappa et al., 2008). This speculation has been supported by the fact that the roots of a sorghum cultivar with more efficient colonization of N2-fixing free-living bacteria exude more malate (Krotzky et al., 1986, 1988). Hence, greater secretion of malate from soybean roots at less acidic pH might provide more carbon for beneficial microorganisms, such as rhizobia and mycorrhizal fungi. We also found that low pH significantly reduced both malate exudation and malate content in soybean root tips (Fig. 3). Reduction of malate content as a result of low pH stress has also been reported in the roots of maize and broad bean (Yan et al., 1992). It has been suggested that the reduction of malate content in plant roots might be caused by the decarboxylation of malate for stabilizing cytoplasmic pH when cytoplasmic acidification occurs due to roots growing in an acidic environment (Davies, 1973). Thus, decreasing malate content of roots may constitute an adaptive change to low pH stress. Moreover, the P efficient genotype HN89 always maintained higher root malate content at low pH regardless of the P and Al levels in the solution (Fig. 3B), suggesting it has a greater potential to adapt to acidic soil conditions.

The malate exudation in response to Pi starvation has been suggested as a mechanism for P mobilization in the soil in several plant species grown on acid soils (Hoffland et al., 1989; Hinsinger, 2001; Sas et al., 2001). Although we also observed that low P-grown plants had a higher root malate exudation at low pH than did plants supplied with P, these differences were not as large as those described earlier (Fig. 3A). Increased malate exudation under low P conditions can help to solubilize P that is fixed by Fe and Al oxides in acid soils, thereby enhancing the plant’s adaptation to P deficiency (Hoffland et al., 1992; Sas et al., 2001; Lü et al., 2011). More interestingly, under the combined conditions of low pH, Al toxicity and high P availability in hydroponics, which mimics the conditions of acid soils fertilized at the soil surface with P, the decrease in malate exudation in soybean roots under low pH conditions was alleviated by Al supply, particularly in the P-efficient genotype HN89.
These results strongly suggest that root malate exudation might be the critical mechanism for soybean adaptation to acid soils, and that the control of the expression of the gene encoding the malate transporter underlying these responses, as well as the activity of the transport protein, might be regulated both by Al exposure and plant P status, as well as low external pH.

We cloned a malate transporter (designated *GmALMT1*) from soybean roots treated with Al using degenerate primers derived from the conserved domain of previously cloned malate transporter proteins from wheat, Arabidopsis and rape. The expression of *GmALMT1* was found to be regulated by low pH, Al toxicity and P availability. *GmALMT1* expression was Al-concentration dependent and its expression was only up-regulated by Al in soybean root tips, and not in the mature root regions (Fig. 4A and B). Since root tips are the primary site of Al toxicity where any primary Al tolerance mechanism must reside (Ryan et al., 1992; Delhaize et al., 1993a), this root-tip specific and Al-concentration dependent expression pattern is consistent with the role of GmALMT1 in the efficient detoxification of Al toxicity. The localization to the root tip will greatly reduce the carbon cost to the plant for this tolerance mechanism. Similar Al-activated expression patterns were also observed for *AtALMT1* and *BnALMT1* in Arabidopsis and rape, respectively (Hoekenga et al., 2006; Ligaba et al., 2006). Subcellular localization of GmALMT1 indicated the protein is localized to plasma membrane (Fig. 6). Functional analysis of GmALMT1 in *X. oocytes* also demonstrated that GmALMT1 functions as a plasma membrane transporter capable of mediating malate efflux (Fig. 7 and 8). Although many ALMTs have been characterized, not all of them are involved in plant Al tolerance. The function of GmALMT1 as a malate transporter that mediates root malate exudation is analogous to the same proposed function for related ALMT1 proteins from barley, wheat, Arabidopsis and rape (Sasaki et al., 2004; Hoekenga et al., 2006; Ligaba et al., 2006), but different from ZmALMT1 and ZmALMT2, which function as mineral anion transporters in maize (Piñeros et al., 2007; Ligaba et al., 2012). GmALMT1 is also distinctively different from some other ALMT members, for example AtALMT12 and HvALMT1, which encode guard cell anion channels that facilitate organic anion transport involved in the opening and closing of stomatal complexes in leaves (Gruber et al., 2010; Meyer et al., 2010), or AtALMT9, which is localized to the vacuole, playing a role in the regulation of cytosolic malate homeostasis (Kevermann et al., 2007). In the present study, we have also revealed that GmALMT1 activity is Al-independent, and its transport activity is highly dependent on extracellular pH (Fig. 8), a unique regulatory mechanism not yet described for other ALMT-type transporters. Interestingly, not only was
GmALMT1 transport activity (Fig. 7) regulated by external pH, but also its expression in planta was down-regulated by low pH (Fig. 4C and 5), which closely correlates with the reduction in root malate exudation when the roots were transferred from pH 5.8 to pH 4.3 (Fig. 3A). The response of GmALMT1 to low pH makes GmALMT1 quite distinctive from the other known ALMT genes involved in Al tolerance. In these other ALMTs, including AtALMT1 and TaALMT1, their expression is not influenced by or is slightly increased in response to low pH conditions (Sasaki et al., 2004; Kobayashi et al., 2007; Liu et al., 2009). When subjected to the conditions that mimic the acid soil syndrome of low pH, high Al and variable P supply, the expression of GmALMT1 was suppressed by low pH, but increased by Al and P addition, especially for the P efficient genotype HN89 (Fig. 5).

The functionality of GmALMT1 was also investigated by overexpression in Arabidopsis, as well as altering its expression in soybean using the soybean transgenic hairy root system. Overexpression of GmALMT1 in both soybean hairy roots and Arabidopsis led to greater malate exudation (Fig. 9B and 10B), while knocking down the expression of GmALMT1 in soybean hairy roots by RNAi led to decreased malate exudation from hairy roots (Fig. 10B). Furthermore in both Arabidopsis and soybean hairy roots, these genetically-induced changes in GmALMT1 expression which led to the expected changes in malate exudation, correlated well with changes in Al tolerance. The strong correlation between the different experimental approaches provides solid evidence that GmALMT1 is a plasma membrane root malate efflux transporter that plays a critical role in soybean Al tolerance.

Based on field evaluations as well as physiological and molecular analysis in the laboratory, we conclude that root malate exudation in soybean is coordinately regulated by low pH, Al and P through GmALMT1, which might be the critical mechanism for soybean adaptation to acid soils. Therefore, GmALMT1 could be considered as a potential candidate gene for crop improvement in acid soils through biotechnological approaches.

**MATERIALS AND METHODS**

**Plant Materials and Growth Conditions**

Two soybean (Glycine max L. Merr.) genotypes, HN89 and HN112, contrasting in P efficiency were used in this study. A previous study from our lab established that HN89 is a P efficient genotype, while HN112 is a P inefficient genotype (Zhao et al., 2004).

In the field trial, soybean plants were grown on acidic red soils at the Boluo (E114.28°, N23.18°) field site in the Guangdong Province of China. Basic soil chemical characteristics of the top 20 cm layer were as follows: pH, 5.71; organic matter, 1.76 mg kg⁻¹; available P
(Bray I method), 12.31 mg P kg\(^{-1}\); available nitrogen, 86.64 mg N kg\(^{-1}\); available potassium, 75.28 mg K kg\(^{-1}\). There were two P treatments, including low P (no P added) and high P (80 kg P\(_2\)O\(_5\) ha\(^{-1}\) added as triple super phosphate to the top 10 cm of soil by band application). 80 kg N ha\(^{-1}\) as urea and 80 kg K kg\(^{-1}\) as KCl were used to supply N and K for all plants. The soil samples were separately taken from 3 layers (0-20 cm, 20-40 cm, and 40-60 cm) along the soil profile before planting and their pH values, exchangeable acidity, and exchangeable P, and Al\(^{3+}\) content were measured. The trial was conducted using a randomized block design with six replicates for each treatment. Sixty days after sowing, soybean plants were harvested and total root length and dry weight were determined (Zhao et al., 2004). After being carefully washed, roots were scanned and the total root length was quantified with computer image analysis software (WinRhizo Pro, Régent Instruments, Québec, Canada).

For the hydroponics studies, soybean seeds were sterilized with 10 % (v/v) bleach for 1 min, and germinated in paper rolls in a beaker at 25°C. To maintain the moisture of the germination paper rolls, 1 to 2 cm of one-fourth strength modified Hoagland nutrient solution (pH 5.8) was added into the beaker (Liao et al., 2006). Following three days after germination, the seedlings were transferred to 0.5 mM CaCl\(_2\) with corresponding Al concentration to study the GmALMT1 expression pattern as related to Al and pH value. To test the spatial expression patterns of GmALMT1 in roots, root regions of 0-2, 2-4, and >4 cm from the root tips were separately harvested for qRT-PCR analysis after 6 h of Al exposure. For analyzing dose effects of Al toxicity on GmALMT1 expression, roots of HN89 were exposed to 0, 50, and 100 µM AlCl\(_3\) for 6 h. The first 2 cm root segments from root tips were harvested for qRT-PCR analysis. For assaying temporal expression patterns of GmALMT1 as related to low pH and Al toxicity, seedlings of HN89 were treated with low pH (4.3) for 12 h. For the non-Al-treated samples, the first 2 cm root segments from the root tips were harvested at 0, 6 and 12 h. For the Al treatment samples, after 12 h low pH acclimation, the seedlings were transferred to 50 µM AlCl\(_3\). Root tips were harvested at 2, 4, 6, 8, 10, 12, and 24 h of Al treatment.

To investigate the effects of Al, P and low pH on expression of GmALMT1, root growth, malate exudation and root tip malate content, soybean seeds were germinated separately in P sufficient (250 µM KH\(_2\)PO\(_4\)) and deficient (5 µM KH\(_2\)PO\(_4\)) modified Hoagland nutrient solution (pH 5.8) for 3 days. After germination, seedlings were subjected to fresh nutrient solution with specific pH, Al and P treatments, which partially mimic the real nutrient situation in acid soils. The two pH treatments were pH 4.3 and pH 5.8. The two P treatments
were application of 320 µM (+P) or 0 µM (-P) KH₂PO₄. For Al treatments, seedlings were treated with (+Al) or without (-Al), 38 µM Al³⁺ activity as calculated by the GEOCHEM-EZ speciation software (Shaff et al., 2010). The combinations of the treatments were: +Al/+P/pH4.3, +Al/-P/pH4.3, -Al/+P/pH5.8, -Al/+P/pH4.3, -Al/-P/pH4.3 and -Al/-P/pH5.8.

After 6 h of treatments, the first 2 cm tap root tips were harvested for quantifying *GmALMT1* expression. Relative root length was measured using rulers and determined by the percentage of relative net root growth as described before, using tap root growth under the treatments including -Al/+P/pH5.8 and -Al/-P/pH5.8 as control (Liu et al., 2009). In order to minimize the interference of other nutrient elements in the capillary electrophoresis determinations of malate using, as well as reduce the stress of low-ion strength, measurement of malate exudation and accumulation were performed in 4.3 mM CaCl₂ solution. Soybean seedlings were directly transferred to 4.3 mM CaCl₂ solution including the two P levels (0 and 320 µM KH₂PO₄), two pH levels (4.3 and 5.8), and two Al levels (0 and 38 µM Al³⁺ activity) as mentioned above. All the hydroponic experiments were aerated according to Liao et al (2006). All the treatments had four replicates.

**Determination of Malate Exudation and Accumulation**

To quantify malate exudation from soybean roots, seedlings of both soybean genotypes were subjected to the specific treatments. For all the treatments of Al toxicity, the pH value of solution was adjusted to 4.3. After 6h of treatment, root exudates were collected and frozen at -20°C for further analysis. The first 2 cm from the tips of the tap roots were then harvested for root malate content determinations. Each treatment for different genotypes included four replicates, with each replicate containing four plants.

Secreted malate was processed and measured as described before (Liao et al., 2006). Briefly, the root exudates were passed through a silver cartridge (OnGuardII Ag; Dionex) to remove excess Cl⁻. The pass-through products were then mixed with cation-exchange resin (100:1, v/w) for 10 min to remove cations and make the organic acids fully quantifiable. Following centrifugation, the supernatants were used for malate determination. In order to determine malate content in root tips, root tips were extracted using 18Ω water. After centrifuging at 12,000 rpm for 10 min at 4°C, the supernatants were collected and used for malate content measurement. Malate determinations were conducted on a Beckman-Coulter MDQ capillary electrophoresis system using methods more fully described in Maron et al (2010).

**Isolation and Characterization of *GmALMT1***
Total RNA was extracted from the root tips of the P efficient soybean genotype HN89 subjected to Al toxicity. The degenerate primers (5’-TGGGCIRTIHTIACIGTIGT-3’ and 5’-CCIGCCCAIAYIGGRMA-3’) were designed according to the conserved motifs of ALMTs from Arabidopsis, rape and wheat. A fragment of 405 bp was PCR amplified using the degenerate primers from the cDNA. Subsequently, 5’ and 3’ ends of GmALMT1 were separately amplified using rapid amplification of cDNA ends (RACE) following the Advantage TM 2 PCR Kit manual (CLONTECH, USA) using the following primers were: (5’-GCCTCTTTATGATGGCTTCGGAGTTG-3’; 5’-AATGTGGGCTGTTCTGACGATGGTG-3’; 5’-CAAGTACTGCTCCCAAGGATGGCGA-3’; 5’-GACGGGACAAATGAAAGTGAGATGACC-3’). All the PCR fragments were cloned into a pGEM-T easy vector (Promega, USA) for sequence confirmation. These fragments were analyzed and combined to generate a full length cDNA through the MEGA 4.1 program. Phylogenetic tree analysis was constructed with MEGA4.1.

**Characterization of GmALMT1 Expression**

Expression of GmALMT1 was determined by quantitative reverse transcript PCR (qRT-PCR). Briefly, Total RNA was extracted using Trizol reagent according to the manual (Invitrogen Inc., USA), and treated with DNase I (Invitrogen Inc., USA). Two µg total RNA of each sample was used for the first-strand cDNA synthesis in 20 µL reverse transcript reaction. Reverse transcription was performed according to the manufacture’s protocol (Invitrogen, USA). The first-strand cDNA was used for SYBR Green monitored qRT-PCR (ABI., USA). The qRT-PCR analysis was performed using an Applied Biosystems 7500 Real-Time PCR System (ABI, USA). The primer pairs used for qRT-PCR analysis for GmALMT1 were 5’-GAGCACTTACTCGGGAATGTG-3’ and 5’-GGACCTTTGCGCAGTTG ATGGG-3’, and 5’-TGCAAAGGAGGCTGCTAACT-3’ and 5’-CAGCATCACCCTTCTTC AAA-3’, for housekeeping gene EF-1α. Expression of GmALMT1 was calculated from the relative expression levels of GmALMT1 to expression levels of the reference gene EF-1 using arbitrary units.

**Subcellular Localization of GmALMT1-YFP Fusion Protein**

Subcellular localization was determined via transient expression of translational fusions with YFP in Arabidopsis leaf protoplasts. The coding regions (cDNA) of GmALMT1 was subcloned into the expression vector pSAT6-eYFP-C1 (Tzfira et al., 2005). Transient expression of the YFP::GmALMT1 translational fusion was carried out as described (Yoo et al., 2007). Protoplasts were transformed with 20 µg of plasmid DNA via PEG transformation and incubated in the dark at room temperature overnight. Plasma membrane staining was
achieved by incubation of protoplasts with CellMask Orange (Invitrogen; www.invitrogen.com) at a concentration of 2.5 µg/mL for 15 minutes at 30°C. Imaging was conducted under a Leica TCS SP5 laser scanning confocal microscope (www.leica-microsystems.com). The excitation/emission filter wavelengths for each channel were as follows: GFP: 488 / 500–525 nm; CellMask plasma membrane dye: 561 / 570–586 nm; chloroplast autofluorescence: 561 / 669–694 nm.

**Functional Characterization of GmALMT1 in Xenopus Oocytes**

The coding region of *GmALMT1* was cloned between the *Bgl*II and *Spe*I unique site of the T7TS plasmid. The coding region contained a kosak consensus sequence (GCCGCCACC) immediately upstream of the initiation codon and was flanked by the 3′- and 5′-untranslated regions of a *Xenopus* β-globin gene. The construct was fully sequenced and checked for sequence accuracy. Complementary RNA was synthesized from 1 µg *Sma*I-linearized plasmid DNA template using a mMessage *in vitro* transcription kit (Ambion, http://www.ambion.com/) according to the manufacturer’s recommended procedures, and purified with the MegaClear kit (Ambion), eluted in RNase-free water and stored at -80°C. Harvested and defolliculated stage V–VI *Xenopus laevis* oocytes were maintained as described previously (Piñeros et al., 2008). Oocytes were injected with 50 nL water or 50 nL of water containing 30 ng of GmALMT1 cRNA, and incubated in ND96 at 18°C for 2–3 days prior to electrophysiological measurements.

Whole-cell currents were recorded under constant perfusion with both GeneClamp 500 and Axoclamp900A amplifiers (Axon Instruments, http://www.moleculardevices.com/homr.html) using the two-electrode voltage-clamp (TEVC) technique. The recording electrodes were filled with 0.5 M K₂SO₄ and 30 mM KCl, and had resistances between 0.5 and 1.5 MΩ. The standard bath recording solution contained (in mM) 96 NaCl, 1 KCl, 1.8 CaCl₂ and 0.1 LaCl₃ with the pH adjusted to 7.5 or 4.5. LaCl₃ was included in the bath solution as it effectively attenuates potential voltage dependent hyperpolarization-induced and volume sensitive endogenous oocyte chloride currents (Ackerman et al., 1995; Tokimasa and North, 1996). The later approach has been successful for the characterization of inward currents mediated by several members of the ALMT family of transporters. (Hoekenga et. al, 2006; Ligaba et al., 2012; Piñeros et al., 2008). It’s worth noting that acidification of the bath media can result in highly variable increases in the endogenous outward currents, at holding potentials more positive than + 60mV. Thus, currents under voltage clamp conditions were elicited by a 1 s voltage pulses in 10 mV step increments between +40 and -140 mV, with a
10-s rest at +40 mV between each voltage pulses. The output signal was digitized and
analyzed using Digidatas1320A and 1440APClamp 10 data acquisition systems (Axon
Instruments). The steady-state current–voltage (I/V) relationships were constructed by
measuring the current amplitude at the end of the test pulse. All data points represent the
mean and SE values of at least eight different cells from two to three donor frogs. Error bars
denote SEM and are not shown when they are smaller than the symbol. Intracellular malate
concentrations were modified by injecting 50 nL of varying concentrations (0 to 100 mM) of
Na-malate, resulting in expected free malate intracellular ionic activities (i.e. {mal2}\(^{-}\)) of 1.3, 2.4 and 4.5 as described previously (Ligaba et al., 2012; Piñeros et al., 2008). Slope
conductances of the inward currents were estimated by the linear regression of current values
between -140 and – 100 mV.

**Heterologous Expression of GmALMT1 in Arabidopsis**

A binary plasmid vector was constructed for stable plant transformation with the
GmALMT1 gene under the control of the CaMV35S. The coding region of GmALMT1 was
amplified with primers (5’-GGAAGATCTCATGGATATAGAGTCAACAACCCAAGC-3’
and 5’-CAGCACGCGTCTATTTACAAATTGAATGGAGGGGCA3’), and subcloned into
the BgII/MluI site of the pYLRNAi vector (Liang et al., 2010). The construct was then
transformed into the *Agrobacterium tumefaciens* strain GV3101 by electroporation, which
was then used for *Arabidopsis thaliana* transformation. The expression of GmALMT1 in the
transgenic plants was qualified by qPCR. The Arabidopsis tubulin gene was used as the
internal control using the following two primers (5’-TGTCGTCCAACCTTACAACTCACT-
3’ and 5’-TCTCCAGGGTCCTCCATTCC-3’).

Two representative transgenic homozygous T3 lines were used for determining malate
exudation and Al tolerance. In the transgenic Arabidopsis plants, Al tolerance was
determined by measuring relative root growth. For malate exudation assays, Arabidopsis
seeds were surface sterilized and germinated on solid MS medium for one week. Uniform
seedlings were then transferred to hydroponic MS medium and grown with shaking at 180
rpm. After ten days of incubation, seedlings were washed several times with sterilized water
and the growth media was replaced by a solution consisting of 0.5 mM CaCl\(_2\) (pH 4.3) and no
Al, in order to minimize interference from the endogenous AtALMT1 Al-dependent malate
exudation present in Arabidopsis. After 24 h incubation, the collection solution was sampled
for malate assay. To quantify root growth and the effect of Al toxicity, seeds of wild type
Arabidopsis and two transgenic lines were surface-sterilized and germinated for 4 d on solid
Murashige and Skoog (MS) medium. After germination, uniform seedlings were transferred
to 0.5 mM CaCl$_2$-agar plates containing 0, 400 µM AlCl$_3$, respectively. After 2 d of treatments, plant roots were scanned, and primary root length was measured using the Image J program. The relative root growth was calculated as described (Liu et al., 2009). Each treatment for different lines had four replicates, which each replicate contained four plants.

**Overexpression and Knock-down via RNA Interference of GmALMT1 in Soybean Hairy Roots**

The GmALMT1 transformation vector described above was also used for GmALMT1 expression in soybean hairy roots. The RNA interference construct was made by amplifying the coding region of GmALMT1 with primers (GmMT1RiB: 5’-GGATCCTGGTCGCTGTCTCG-3’; GmMT1RiH: 5’-AAGCTTACATTCCCGAGTAAGTGCT-3’; GmMT1RiP: 5’-CTGCAGACATTCCCGAGTAAGTGCT-3’; GmMT1RiM: 5’-ACGCGTTGGTCGCTGTCTCG-3’), and subcloned into the pYLRNAi vector (Liang et al., 2010). The constructs were then transformed into the Agrobacterium rhizogenes strain K599, which was used for soybean hairy root transformation.

The transgenic soybean composite plants with wild type shoots and transgenic roots were developed according to Kereszt et al (2007). Soybean hairy roots transformed with empty vectors were used as control. The hairy roots from three weeks after transformation were used for further analysis. RNA was extracted from hairy roots and qRT-PCR was used to quantify the GmALMT1 expression in both transgenic lines and in the control lines. Four independent lines of each construct were used for the determination of malate exudation. Composite plants were exposed to 4.3 mM CaCl$_2$ (pH 4.3) for 6 h and root exudates were collected and processed for the malate measurement. To detect the function of GmALMT1 as related to Al detoxification, soybean hairy roots were subjected to 0.5 mM CaCl$_2$, pH 4.3, containing 50 µM Al. After 3 h incubation, the hairy roots were then stained with hematoxylin as described by Delhaize et al (1993a). Briefly, the hairy root tips were first washed for 30 min with distilled water, then stained with hematoxylin for 30 min. After staining, the root tips were washed for a further 30 min in distilled water, and then photographed.

**Statistical Analysis**

All of the data were analyzed statistically using Microsoft Excel 2000 (Microsoft Company, USA) for calculating mean and standard error and SAS (SAS Institute Inc., Cary, NC, USA) for ANOVA and Pearson linear correlation analysis between malate exudation and GmALMT1 expression.

Immobilization of aluminum with phosphorus in roots is associated with high
aluminum resistance in buckwheat. Plant Physiol 138: 297–303
Figure 1. Total root length (A) and total plant dry weight (B) for the P efficient (HN89) and P inefficient (HN112) soybean genotypes grown on acid soils with two different P applications. Plants were grown on acid soils under low P (no P added) and high P (80 kg P$_2$O$_5$ ha$^{-1}$ added as triple super phosphate) conditions for 60 d. Each bar represents the mean of six replicates plus the standard error. Asterisks indicate significant differences between two genotypes in the same treatment. *: $P<0.05$; **: $0.001<P<0.01$; ***: $P<0.001$.

Figure 2. Root growth was influenced by pH, Al and P in both soybean genotypes. Al-resistance was based on relative root growth calculated as the root growth under +Al conditions relative to the root growth under –Al conditions. Low pH-based relative root growth was calculated as the root growth for plants grown on nutrient solution at pH 4.3 relative to the root growth of plants grown in nutrient solution at pH 5.8. Phosphate treatments (–P and +P) represent application of 0 and 320 µM KH$_2$PO$_4$, respectively; -Al and +Al indicate application of 0 and 38 µM Al$^{3+}$ activity, respectively. Each value is the mean of four replicates with standard error. Asterisk indicates significant difference between the two genotypes at the same treatment. *: $P<0.05$; **: $0.001<P<0.01$; ***: $P<0.001$.

Figure 3. Root malate exudation (A) and malate content in root tips (B) as influenced by pH, Al and P, in both soybean genotypes. -P and +P represent application of 0 and 320 µM KH$_2$PO$_4$; the pH treatments are pH 4.3 and pH 5.8; -Al and +Al indicate application of 0 and 38 µM Al$^{3+}$ activity, respectively. Each data point is the mean of four replicates with standard error. Asterisk indicates significant difference between two genotypes in the same treatment. *: $P<0.05$; **: $0.001<P<0.01$; ***: $P<0.001$.

Figure 4. Expression pattern of GmALMT1 in response to low pH and Al toxicity. A) Spatial expression pattern of GmALMT1 in soybean tap roots with or without 50 µM AlCl$_3$. B) Al-dose response of GmALMT1 in root tips (0-2 cm). Seedlings were separately treated with 0, 50 and 100 µM AlCl$_3$ for 6 h. C) Temporal expression pattern of GmALMT1 in root tips (0-2 cm) in response to a pH shift from 5.8 to 4.3, followed by addition of Al. Seedlings were subjected to low pH (4.3) for 12 h, and subsequently transferred to the same solution containing 50 µM AlCl$_3$ for up to 24 h. Each data point is the mean of four replicates with standard error.

Figure 5. GmALMT1 expression in root tips (0-2 cm) appears to be coordinately regulated by pH, Al and P. -P and +P represent application of 0 and 320 µM KH$_2$PO$_4$; the pH treatments...
are pH 4.3 and pH 5.8; -Al and +Al indicate application of 0 and 38 µM Al\(^{3+}\) activity, respectively. Al treatments were performed for 6 h. Each data point is the mean of four replicates with standard error. Asterisk indicates significant difference between two genotypes in the same treatment. *: \(P<0.05\); **: \(0.001<P<0.01\); ***: \(P<0.001\).

**Figure 6.** Cellular localization of the GmALMT1 protein in Arabidopsis protoplasts. The first two columns show representatives cells transformed with pSAT6-EYFP-C1 empty vector (as a control) or YFP::GmALMT1, respectively. Rows shows YFP fluorescence, chloroplast autofluorescence, bright field image, as well as overlays are as indicated on the left margin. The third column shows a representative images of YFP::GmALMT1 transformed cells where the plasma membrane has been stained with CellMask (third row, visible as blue fluorescence). All images are representative of 3 independent experiments in which \(\geq 15\) protoplasts were imaged. Scale bar = 20 µM.

**Figure 7.** Functional characterization of GmALMT1 expressed in *X. laevis* oocytes. A) Resting membrane potentials (RMP) of GmALMT1-expressing and control cells measured in standard bath solution at pH 7.5 and 4.5. B) Example of GmALMT1-mediated currents (right panels) elicited in response to holding potentials ranging from +40 to -140 mV (in 20 mV increments) in standard bath solution at pH 7.5 and 4.5. The voltage was held at +40mV for 10s between each voltage pulse. Currents recorded in control cells (i.e. not injected with cRNA) are shown for reference on the left of panels. The dotted line and arrow on the left margin indicates the zero current level. C) Mean current-voltage (\(I/V\)) curves constructed from the steady-state currents recordings such as those shown in (B) for holding potentials ranging from +40 mV to -140 mV in 10 mV steps. The symbols correspond to those depicted above the example traces in part B.

**Figure 8.** Effects of intracellular malate activities and extracellular pH on GmALMT1-mediated currents expressed in *Xenopus* oocytes. Two to three hours prior to the electrophysiological measurements, cells were preloaded with 50 nL of Na-malate solution (pH 7.2) resulting in internal malate free activities ranging from 0 to 4.5 mM. A) Example of GmALMT1-mediated currents elicited in response to the voltage protocol described in Figure 7B, as extracellular pH (7.5: left panel and 4.5: right panel) and internal malate free activities (\(\{\text{mal}^2\}\)_1 denoted on the top of each set of traces) were varied. The dotted line and arrow on the left margin indicates the zero current level. B) Mean current-voltage (\(I/V\)) curves constructed from the steady-state currents recordings such as those shown in (A) for GmALMT1-expressing cells at various \(\{\text{mal}^2\}\)_1 in standard bath solutions at pH 7.5 (left panel) and 4.5 (right panel). The symbols correspond to those depicted above the example traces.
traces in panel A. Values for control cells (white squares) and GmALMT1 cells not preloaded with malate (white triangles) correspond to those shown in Figure 7. C) Analysis of GmALMT1-mediated inward conductances in response to changes in extracellular pH and increasing \{\text{mal}^2\}. The inward conductances were estimated by the linear regression of the current at the four most negative potentials. The curves were drawn according to the Hill equation \(G = G_{\text{max}} \times \frac{([\text{mal}]^n)}{([\text{mal}]^n) + K^n}\), where \([\text{mal}]^n\) stands for the internal malate activity, \(G_{\text{max}}\) is the maximum conductance and \(K\) is the internal malate activity where the conductance reach half their maximum value. Best fit resulted in \(K = 0.9 \pm 0.2\, \text{mM}, G_{\text{max}} = 14 \pm 1\, \text{nS}, \) and \(n = 1.1 \pm 0.32\) (\(R^2 = 0.934\)) at pH 7.5, and \(K = 0.6 \pm 0.1\, \text{mM}, G_{\text{max}} = 8 \pm 1\, \text{nS}, \) and \(n = 0.87 \pm 0.11\) (\(R^2 = 0.988\)) at pH 4.5. The inward slope conductance for control cells at pH 4.5 is indicated by the asterisks. D) The increase in the magnitude of the GmALMT1-mediated inward current upon increasing intracellular malate is concurrent with a positive shift in the reversal potential (\(E_{\text{rev}}\) noted by the dashed lines). Whole cell currents were elicited by a voltage ramp protocol from -140 mV to + 40 mV (0.9 s duration), from a holding potential of + 40 mV, in standard bath solution (pH 7.5). The currents shown are representative of those obtained in ramp trials of cells (n=5) not loaded (0 mM) or preloaded (n=6) with malate (\{\text{mal}^2\}_i = 4.5\, \text{mM}) as indicated next to each ramp.

**Figure 9.** Al tolerance is enhanced by heterologous expression of *GmALMT* in transgenic Arabidopsis plants. A) *GmALMT1* expression in the two transgenic lines (OX1 and OX2) and CK line; B) Malate exudation of transgenic Arabidopsis and CK plants under low pH condition; C) Root growth performance and D) Relative root growth of the plants subjected to 400 µM Al for 2 d. All the data represent the means of four replicates with standard errors. Asterisk indicates significant difference from the CK. *: \(P < 0.05\); **: \(0.001 < P < 0.01\); ***: \(P < 0.001\).

**Figure 10.** *GmALMT1* expression (A), malate exudation (B) and Al tolerance (C) of the composite soybean transgenic hairy roots under the low pH (pH 4.3) conditions. Root malate exudation was measured after the roots were exposed to 4.3 mM CaCl$_2$ (pH 4.3) for 6 h. Root tips stained with the Al stain, hematoxylin, was used as an indicator of Al tolerance. GmALMT1-KD and GmALMT1-OX represent *GmALMT1* RNA interference and overexpression lines, respectively. The lines transformed with empty vector were used as control (CK). All the data are the means of four biological replicates with standard errors. Asterisk indicates significant difference. *: \(P < 0.05\); **: \(0.001 < P < 0.01\); ***: \(P < 0.001\). Bars= 1mm.
