25.75.NqQuark deconfinement, quark-gluon plasma production, and phase transitions
25.75.-q Relativistic heavy-ion collisions
25.75.Dw Particle and resonance production

Abstract. Using an advanced version of the hadron resonance gas model we have found remarkable irregularities of relativistic heavy-ion collisions at chemical freeze-out. They include an abrupt change of the effective number of degrees of freedom at laboratory energies 8.9–11.6 AGeV and plateaus in the collision-energy dependence of the entropy per baryon, total pion number per baryon, and thermal pion number per baryon at laboratory energies 6.9–11.6 AGeV. Also at chemical freeze-out we observe a sharp peak in the dimensionless trace anomaly at laboratory energy 11.6 AGeV. On the basis of the generalized shock-adiabat model we demonstrate that these observations give evidence for the anomalous thermodynamic properties of the mixed phase at its boundary to the quark-gluon plasma. We argue that the trace anomaly peak and the local minimum of the generalized specific volume observed at a laboratory energy of 11.6 AGeV provide a signal for the formation of a mixed phase between the quark-gluon plasma and the hadron phase.
I. INTRODUCTION

In the last thirty years of searching for the quark-gluon plasma (QGP) in heavy-ion collision experiments many signals of its formation were suggested, but neither direct evidence for QGP formation nor a clear signal of a QGP-hadron mixed phase have been observed so far. Although some irregularities, known in the literature as the Kink [1], the Strangeness Horn [2], and the Step [3], were observed and are often advocated as signals of the onset of deconfinement [4], their relation to the QGP-hadron mixed phase is far from being clear. Therefore, additional and independent justification of these irregularities is required. This task is rather important in view of the planned heavy-ion collision experiments at JINRNICA and GSI-FAIR. Clearly, searching for other irregularities and signals of mixed phase formation is no less significant, but until recently such efforts were not very successful, since they require a realistic model which is able to accurately describe the existing experimental data and, thus, provide us with reliable information about the late stages of the heavy-ion collision process.

The recent extensions [5–8] of the hadron resonance gas model [9–14] provide us with the most successful description of available hadronic multiplicities measured in heavy-ion collisions at AGS, SPS, and RHIC energies. The global values of $\chi^2/dof \simeq 1.16$ and $\chi^2/dof \simeq 1.06$ achieved, respectively, in Refs. [6] and [7] for 111 independent multiplicity ratios measured at 14 values of the center-of-mass energy $\sqrt{s_{NN}} = 2.7, 3.3, 3.8, 4.3, 4.9, 6.3, 7.6, 8.8, 9.2, 12, 17, 62.4, 130, 200$ GeV (for more details, see Ref. [6, 7]) give us confidence that the irregularities found in the narrow range of collision energies $\sqrt{s_{NN}} = 4.3 - 4.9$ GeV are not artifacts of the model and indeed reflect reality.

However, the most difficult part of establishing a signal of mixed phase formation is to formulate a convincing model of the heavy-ion collision process, which allows to connect the irregularity in the behavior of some observable with the occurrence of the QGP-hadron phase transition. Here we report such remarkable irregularities as an abrupt change of the effective number of degrees of freedom and a peak of the trace anomaly $\delta$, which are seen at $\sqrt{s_{NN}} = 4.9$ GeV, and plateaus in the collision-energy dependence of the entropy per baryon, total pion number per baryon and thermal pion number per baryon found at laboratory energies 6.9–11.6 AGeV ($\sqrt{s_{NN}} = 3.8 - 4.9$ GeV). We observe all these irregularities at the stage of chemical freeze-out (FO) using the most successful version of the hadron resonance
gas model [5][8]. However, in order to relate them to the QGP-hadron phase transition we employ the model of the generalized shock adiabats for central nuclear collisions [15][17], which predicted such plateaus a long time ago.

Surprisingly, at chemical FO we also observe a second set of plateaus at higher laboratory energies 30–44 GeV ($\sqrt{s_{NN}} = 7.6 – 9.2$ GeV), where the generalized shock-adiabat model is no longer reliable, but which is exactly the region where the onset of deconfinement is claimed to exist [1][4][18]. On the one hand, this fact demonstrates that despite the large error bars the performed analysis of the entropy per baryon, total pion number per baryon, and thermal pion number per baryon extracted from the data at chemical FO is able to detect hidden correlations between the plateaus in these quantities. On the other hand, if the plateaus at laboratory energies 30–44 GeV are also generated by a mixed phase instability, as it is the case for the set of plateaus found at lower collision energies, then this may provide evidence for a second phase transition.

In addition, here we not only discuss the physical origin of novel signals of mixed phase formation such as the minimum of the generalized specific volume and the sharp peak of the trace anomaly, we also relate them to the observed irregularities in the total pion number per baryon.

This work is organized as follows. In the next section we report various irregularities existing at chemical FO. In order to provide a possible interpretation, in section 3 we present a short discussion of the generalized shock model and the possible origin of the above mentioned plateaus in the entropy per baryon, the total pion number per baryon, and the thermal pion number per baryon. We also present the details of extracting the parameters of the plateaus from the data and from the chemical FO quantities. Section 4 is devoted to a justification of new signals of QGP-hadron mixed phase formation, while our conclusions are summarized in section 5.

II. NOVEL IRREGULARITIES AT CHEMICAL FO

In order to elucidate the irregularities at chemical FO we employ a multicomponent hadron resonance gas model (HRGM) [5][6] which currently provides the best description of the observed hadronic multiplicities. Hadron interactions are taken into account via hard-core repulsion, with different hard-core radii for pions, $R_\pi$, kaons, $R_K$, other mesons, $R_m$, ...
FIG. 1: The particle-yield ratios described by the present multi-component HRGM. The best fit for $\sqrt{s_{NN}} = 3.8$ GeV (AGS) is found for $T \simeq 84.0$ MeV, $\mu_B \simeq 618.5$ MeV, $\mu_{I3} \simeq -13.3$ MeV, yielding $\chi^2/dof = 0.56/2 = 0.28$, whereas for $\sqrt{s_{NN}} = 4.3$ GeV (AGS) it is found for $T \simeq 95.3$ MeV, $\mu_B \simeq 586.7$ MeV, $\mu_{I3} \simeq -16.2$ MeV, with $\chi^2/dof = 0.35/2 = 0.175$.

and baryons, $R_b$. The best global fit of all hadronic multiplicities was found for $R_b = 0.2$ fm, $R_m = 0.4$ fm, $R_\pi = 0.1$ fm, and $R_K = 0.38$ fm \[6\]. More details about this HRGM can be found in Refs. \[5\] \[8\].

In the HRGM the full chemical potential of the $i$-th hadron species, $\mu_i \equiv Q_i^B \mu_B + Q_i^S \mu_S + Q_i^{I3} \mu_{I3}$, is expressed in terms of the corresponding charges $Q_i^K$ and their chemical potentials. For each collision energy the fit parameters are the temperature $T$, the baryonic chemical potential $\mu_B$, and the chemical potential of the third component of isospin $\mu_{I3}$, whereas the strange chemical potential $\mu_S$ is found from the condition of vanishing strangeness.

Another important feature of the employed HRGM is that the width of all hadron resonances is taken into account. A thorough discussion of its role can be found in Ref. \[8\]. As usual, the effect of the resonance decay $Y \rightarrow X$ on the final hadron multiplicity is taken into account as $n_{fin}(X) = \sum_Y BR(Y \rightarrow X)n_{th}(Y)$, where $BR(X \rightarrow X) = 1$ for the sake of convenience. The masses, the widths, and the strong-decay branchings of all experimentally known hadrons were taken from the particle tables used by THERMUS \[19\].

In this work we use the data set of Ref. \[6\]. At AGS energies ($\sqrt{s_{NN}} = 2.7 - 4.9$ GeV
FIG. 2: The same as in Fig. 1, but for $\sqrt{s_{NN}} = 4.9$ GeV (AGS) the fit gives $T \simeq 127.0$ MeV, $\mu_B \simeq 530.8$ MeV, $\mu_{I3} \simeq -18.4$ MeV, and $\chi^2/dof = 0.5/5 = 0.11$, whereas for $\sqrt{s_{NN}} = 6.3$ GeV (SPS) one finds $T \simeq 130.1$ MeV, $\mu_B \simeq 430.4$ MeV, $\mu_{I3} \simeq -15.6$ MeV, and $\chi^2/dof = 7.91/6 = 1.32$. or $E_{lab} = 2.9 - 11.6$ GeV per nucleon) the available data have a good energy resolution. However, for the beam energies 2, 4, 6, and 8 GeV per nucleon only a few data points are available. They correspond to the yields for pions [20, 21], for protons [22, 23], and for kaons [21] (except for 2 GeV per nucleon). $4\pi$–integrated data are also available for $\Lambda$ hyperons [21] and for $\Xi^-$ hyperons (for 6 GeV per nucleon only) [25]. However, as it was argued in Ref. [13], the data for $\Lambda$ and $\Xi^-$ should be recalculated for midrapidity. Therefore, instead of raw experimental data we used the corrected values from Ref. [13]. Furthermore, we analyzed the data set at the highest AGS energy ($\sqrt{s_{NN}} = 4.9$ GeV or $E_{lab} = 11.6$ GeV per nucleon). Similarly to Ref. [6], here we analyzed only the NA49 mid-rapidity data [26–31], being the most difficult ones to reproduce. Since RHIC high-energy data of different collaborations agree well with each other, we analyzed the STAR results for $\sqrt{s_{NN}} = 9.2$ GeV [32], $\sqrt{s_{NN}} = 62.4$ GeV [33], $\sqrt{s_{NN}} = 130$ GeV [34–37], and 200 GeV [37–39].

These experimental data were chosen because of their completeness and consistency. The fit criterion is a minimization of $\chi^2 = \sum_i \frac{(r_i^{\text{theor}} - r_i^{\text{exp}})^2}{\sigma_i^2}$, where $r_i^{\text{theor}}$ and $r_i^{\text{exp}}$ are, respectively, theoretical and experimental values of particle-yield ratios, $\sigma_i$ stands for the corresponding experimental error, and a summation is performed over all independent experimental ratios.
FIG. 3: Energy dependence of entropy density (circles) and temperature (squares) at chemical freeze-out extracted from hadron multiplicities measured in heavy-ion collisions at AGS ($E_{lab} < 15$ GeV), SPS ($E_{lab} > 15$ GeV), and RHIC ($E_{lab} = 44$ GeV).

For an extended discussion of the independent hadron-multiplicity ratios see Refs. [6, 13].

Within the present HRGM, a global value of $\chi^2/dof \simeq 1.16$ [6] is obtained for 111 independent multiplicity ratios measured at AGS, SPS, and RHIC, at the 14 values of collision energy specified above. Some results are shown in Figs. 1 and 2. As one can see from Figs. 1 and 2, AGS and SPS data are described with very high quality and, hence, using the fit parameters found we were able to extract all thermodynamic quantities at chemical FO.

The most remarkable results are depicted in Figs. 3, 4, and 5. From Fig. 3 one can see that the entropy density $s$ increases by a factor of four in a range of laboratory energies per nucleon $E_{lab} \simeq 8.9 - 11.6$ GeV. At the same time, the chemical FO temperature changes from 95 to 127 MeV and the baryonic chemical potential $\mu_B$ drops only from 586 to 531 MeV. In other words, for a 30% increase in the laboratory energy the ratio $s/T^3$ increases by 70%. A similar change can be seen in the effective number of degrees of freedom in the same energy range, cf. Fig. 4 for the chemical FO pressure in units of $T^4$. Note that a similar (and a somewhat stronger) rapid change in the number of effective degrees of freedom is observed in the most recent (former) version of the hadron resonance gas model [7, 8] ([5, 13]).

As one can see from Fig. 4 at chemical FO a dramatic change is experienced by the so-called generalized specific volume $X = \frac{\varepsilon + p}{\mu_B}$, where $\varepsilon$ is the energy density, $p$ the pressure,
FIG. 4: Energy dependence of the chemical freeze-out pressure (circles), the effective number of degrees of freedom (squares), and the generalized specific volume $X$ found by the present HRGM for the data measured at AGS ($E_{\text{lab}} < 15$ GeV), SPS ($E_{\text{lab}} > 15$ GeV), and RHIC ($E_{\text{lab}} = 44$ GeV).

and $\rho_B$ the baryonic charge density. It is remarkable that in all known examples of equations of state (EOS) describing the QGP-hadron transition a local minimum in the energy dependence of the $X$ values of matter described by the shock or generalized shock model is observed right at the transition to the QGP, independently of whether this is a first-order phase transition [15–17, 40] or a strong cross-over [15, 40]. Therefore, below we would like to reanalyze the generalized shock-adiabat model developed in Refs. [15–17, 40, 41] in order to interpret the above irregularities and to verify the other signals of mixed phase formation.

Another astonishing irregularity, the behavior of the dimensionless trace anomaly $\delta = \frac{\varepsilon - 3p}{T^4}$, is shown in Fig. 5. Note that the inflection point/maximum of the trace anomaly is traditionally used in lattice QCD to determine the pseudocritical temperature of the crossover transition [42]. Figure 5 shows that a sharp peak of the trace anomaly exists exactly at the center-of-mass energy $\sqrt{s_{NN}} = 4.9$ GeV and it is not a coincidence that it occurs right
FIG. 5: Energy dependence of the dimensionless trace anomaly $\delta$ at chemical FO found within the HRGM with the same hard-core radius 0.3 fm for all hadrons [5] (triangles) and with the set of hadronic hard-core radii found in Ref. [6] and employed here (squares). The peak at $\sqrt{s_{NN}} = 4.9$ GeV (AGS) looks very similar to the trace-anomaly peak reported by lattice QCD. 

at this energy, since $\delta$ is directly related to the partial derivatives of the effective number of degree of freedom $\frac{p}{T^4}$ as

$$\delta \equiv T \frac{\partial}{\partial T} \left( \frac{p}{T^4} \right) + \mu_B \frac{\partial}{\partial \mu_B} \left( \frac{p}{T^4} \right) + \mu_I^3 \frac{\partial}{\partial \mu_I^3} \left( \frac{p}{T^4} \right). \quad (1)$$

Therefore, we face the intriguing possibility to relate the peak of the trace anomaly at chemical FO with its peak at the phase transition. In the next sections we will do this using the shock-adiabat model for central nuclear collisions. Also it is necessary to mention that, in order to see the peak of $\delta$ in Fig. 5, it is rather important to account for the non-zero width of all hadronic resonances [8].

III. GENERALIZED SHOCK-ADIABAT MODEL

The generalized shock-adiabat model was developed in Refs. [15] [17] [40] [41] to extend the compression-shock model [43] [47] for regions of matter with anomalous thermodynamic properties. Similarly to nonrelativistic hydrodynamics [48], in the relativistic case matter
is thermodynamically normal, if the quantity \( \Sigma \equiv \left( \frac{\partial^2 p}{\partial X^2} \right)_{s,\rho_B}^{-1} \) is positive along the Poisson adiabat. Otherwise, for \( \Sigma < 0 \), the matter has thermodynamically anomalous properties. The sign of \( \Sigma \) defines the type of allowed simple and shock waves: for \( \Sigma > 0 \) rarefaction simple waves and compression shocks are stable. In the case of an anomalous medium, \( \Sigma < 0 \), compressional simple waves and rarefaction shocks are stable. If both signs of \( \Sigma \) are possible, then a more detailed investigation of the possible flow patterns is necessary [15, 17]. In fact, all known pure phases have thermodynamically normal properties [48], whereas anomalous properties may appear at a first-order phase transition [49, 50], at its second-order critical endpoint [48] or for a fast cross-over [15].

The compression-shock model of central nuclear collisions [43–47] allows one to determine the initial conditions for the subsequent hydrodynamic evolution. Such a picture of the collision process, which neglects the nuclear transparency, can be reasonably well justified at intermediate collision energies per nucleon \( 1 \text{ GeV} \leq E_{\text{lab}} \leq 20 \text{ GeV} \). Its validity in this region of collision energies was once more demonstrated recently [51] within the hydrodynamic model with a realistic EOS. The direct comparison of the results of the compression-shock model with those of the three-fluid model [52] made in Ref. [51] shows that at laboratory energies per nucleon up to \( 30 \text{ GeV} \) this model can be used for quantitative estimates, while at higher energies it provides a qualitative description only. Moreover, this comparison shows that at \( E_{\text{lab}} \leq 30 \text{ GeV} \) transparency effects are not so strong, at least in central nucleus-nucleus collisions.

In the center-of-mass frame of the two colliding nuclei the initial state of the collision can be considered as a hydrodynamic Riemann problem of an initial discontinuity. For normal media this kind of initial discontinuity leads to an appearance of two compression shocks that move in opposite directions toward the vacuum, leaving high-density matter at rest behind the shock fronts. The thermodynamic parameters \( X, p, \rho_B \) of this compressed matter are related by the Rankine-Hugoniot-Taub (RHT) adiabat [48] with the parameters of uncompressed matter in the state \( (X_0, p_0, \rho_{B0}) \),

\[
\rho_B^2 X^2 - \rho_{B0}^2 X_0^2 = (p - p_0) (X + X_0) .
\]

This equation follows from the usual hydrodynamic conservation laws of energy, momentum, and baryonic charge across the shock front. The variable \( X \) is convenient, since with its help the conserved baryonic current can be expressed as \( j_B^2 = -\frac{p - p_0}{X - X_0} \), i.e., in the \( X - p \) plane the
FIG. 6: Schematic picture of the compression RHT adiabat 0-1-2-4 (solid curve) of W-kind \[15\] in the \(X - p\) plane. It is calculated for an EOS with first-order phase transition as discussed in the text. The segments 0-1, 1-2, and 2-4 of the adiabat correspond to the hadronic, mixed, and QGP phases, respectively. Shock transitions into the region of states 1-2-4 are mechanically unstable.

state existing behind the shock front is given by the intersection point of the RHT adiabat \[2\] and the straight line with the slope \(j_B^2\) known as the Raleigh line. In order to solve Eq. \[2\] one needs to know the EOS.

Traditionally, it is believed that the compression-shock model requires immediate thermalization. However, we would like to stress that the hydrodynamic conservation laws should be obeyed irrespectively of whether matter is in thermodynamic equilibrium or not. Moreover, the propagation of the compression shock (or a more complicated hydrodynamic solution) requires a finite formation time \(t_{\text{form}}\) which in the center-of-mass frame of the collision is essentially larger than the propagation of light along the Lorentz-contracted nucleus of diameter \(d\), i.e.,

\[ t_{\text{form}} > \frac{d}{\gamma_0} = \frac{d}{\sqrt{1 + E_{\text{lab}}/(2m_N)}} \]

(here, \(m_N\) is the mean nucleon mass). More accurate estimates for the time of the collision can be found in Ref. \[15\], but the order of magnitude of the above estimate should be correct. Hence, for \(E_{\text{lab}} = 10\) GeV and for \(E_{\text{lab}} = 30\) GeV one finds \(t_{\text{form}} > d/2.5 \approx 4.7\) fm
FIG. 7: Schematic picture of the generalized shock adiabat 0-1-2-3-4 (solid curve) of W-kind [15] in the $X - p$ plane. The segments 0-1, 1-2, and 2-4 of the adiabat correspond to the hadronic, mixed, and QGP phases, respectively. Shock transitions into the region of states 1-2-3-4 are not allowed. The generalized solutions corresponding to these segments are discussed in the text. The dashed line 1-3 is the tangent line in the left vicinity of the point 1.

and $t_{form} > d/4.1 \approx 2.9$ fm, respectively, where we used $d = 12$ fm. In other words, this formation time is rather long on the scale of the strong interaction and, hence, after this time the major part of matter formed in the central zone of the collision has a good chance to become equilibrated, even if it was initially out of equilibrium. Consequently, if only a small amount of energy dissipates during the formation time, it is reasonable to assume that the formed matter can be described by the usual hydrodynamic conservation laws for a perfect fluid [48].

In the compression-shock model the laboratory energy per nucleon is

$$E_{lab} = 2m_N \left[ \frac{(\varepsilon + p_0)(\varepsilon_0 + p)}{(\varepsilon + p)(\varepsilon_0 + p_0)} - 1 \right].$$

A typical example for the shock adiabat is shown in Fig. 6. As one can see from this figure the shock adiabat in the pure hadronic and QGP phases exhibits the typical (concave) behavior for a normal medium, while the mixed phase (the region 1-2) in Fig. 6 has a convex shape which is typical for matter with anomalous properties. Until now there is
no complete understanding why in a phase-transition or cross-over region matter exhibits anomalous thermodynamic properties. In pure gaseous or liquid phases the interaction between the constituents at short distances is repulsive and, hence, at high densities the adiabatic compressibility of matter \(-\frac{\partial X}{\partial p}_{s/p_B}\) usually decreases for increasing pressure, i.e., \((\frac{\partial^2 p}{\partial X^2})_{s/p_B}^{-1} = \Sigma > 0\). In the mixed phase there appears another possibility to compress matter: by converting the less dense phase into the more dense one. As it was found for several EOS with a first-order phase transition between hadronic gas and QGP, the phase transformation leads to an increase of the compressibility in the mixed phase at higher pressures, i.e., to anomalous thermodynamic properties. The hadronic phase of the aforementioned EOS was described by the Walecka model [53] and by a few of its more realistic phenomenological generalizations [17, 51, 54]. The appearance of anomalous thermodynamic properties for a fast cross-over can be understood similarly, if one formally considers the cross-over states as a kind of mixed phase (but without sharp phase boundary), in which, however, none of the pure phases is able to completely dominate.

From Fig. 6 one sees that the presence of anomalous matter leads to mechanically unstable parts of the RHT adiabat (segment 1-2-3 in Fig. 6), which include states in the mixed and the QGP phases. This is a model of W-kind [17, 51, 53] and its RHT adiabat in the instability region should be replaced by the generalized shock adiabat (see Fig. 7) [15, 17]. For W-kind models with unstable parts of the shock adiabat as shown in Fig. 6 the RHT adiabat should be replaced by the generalized shock adiabat schematically depicted in Fig. 7. In this case, in the region of instability 1-2-3 the shock wave has to be replaced by the following hydrodynamic solution [15] of the generalized shock adiabat shown in Fig. 7: a shock between states 0 and 1 (see the upper panel of Fig. 8), followed by a compressional simple wave (see the lower panel of Fig. 8) for the segment 1-2 of the generalized shock adiabat of Fig. 7; at higher energies (segment 2-3 of the generalized shock adiabat of Fig. 7) this solution converts into two compressional shocks and a compressional simple wave moving between them shown in the upper panel of Fig. 9; at even higher energies (segment 3-4 of the generalized shock adiabat of Fig. 7) there exist two compressional shocks following one after the other [15, 43], i.e., a double shock wave as shown in the lower panel of Fig. 9. Note that the double-shock solution was already suggested a long time ago [55].

A similar situation occurs in the case of a fast cross-over or for the RHT adiabat of the W-kind shown in Fig. 10 (see also Figs. 3 and 4 in Ref. 15 for more details) which has
FIG. 8: Upper panel: Sketch of the energy density profile for a collision of two nuclei (grey areas) that corresponds to stable shock transitions (segments 0-1 and above point 4) of the generalized shock adiabat of Fig. 7. The dashed arrows show the direction of shock propagation. Lower panel: Same as in the upper panel, but for the segment 1-2 of the generalized shock adiabat of Fig. 7. Two shocks between the states $\varepsilon_0 \rightarrow \varepsilon_1$ are followed by compressional simple waves.

It is necessary to stress that all these generalized hydrodynamic solutions are proven to be mechanically stable [15, 40, 41] and they were constructed in such a way that all neighboring shocks and simple waves are moving with the same velocity in the rest frame of the Chapman-Jouguet point $A_2$ (see Fig. 10). From Fig. 10 one sees that the presence of anomalous matter leads to mechanically unstable parts of the RHT adiabat (segment $A_2BC$ in Fig. 10), which include states in the mixed and the QGP phases. The only difference with the case of the unstable RHT adiabat of Fig. 7 is that the double shock does not appear due to an instability, while the other solutions shown in Fig. 8 and in the upper panel of Fig. 9 remain the same.
FIG. 9: Upper panel: Sketch of the energy density profile for a collision of two nuclei (grey areas) that corresponds to the states belonging to the segment 2-3 of the generalized shock adiabat of Fig. 7. The dashed arrows show the direction of shock propagation. Between each pair of shocks exists a simple wave. Lower panel: Same as in the upper panel, but for the segment 3-4 of the generalized shock adiabat of Fig. 7. In this case on each side there is a double shock between the states $\varepsilon_0 \rightarrow \varepsilon_1$ and $\varepsilon_1 \rightarrow \varepsilon_D$.

In case of the double shock the inner shock between the initial state 1 and the final state belonging to the segment 3-4 of the generalized shock adiabat of Fig. 7 propagates in the medium 1 slower than the shock between the states 0 and 1 [15, 40, 41].

Shock transitions to mechanically unstable regions are accompanied by a thermodynamic instability, i.e., the entropy in such transitions decreases, while the collision energy grows [15, 49, 50]. At the same time the mechanical stability condition of the generalized shock adiabat always leads to thermodynamic stability of its flows. Or in other words, along the correctly constructed generalized shock adiabat the entropy cannot decrease [41].
FIG. 10: The compression RHT adiabat OA2BC (solid curve) of W-kind in the $X - p$ plane. It is calculated for the EOS with first-order phase transition discussed in the text. The segments OA1, A1B, and BC of the adiabat correspond to the hadronic, mixed, and QGP phases, respectively. Shock transitions into the region of states A2BC are mechanically unstable. The tangent point A2 to the shock adiabat is the Chapman-Jouguet point [48]. The dotted and dashed-dotted curves show the Poisson adiabats with values of entropy per baryon specified in the legend. See insert figure for details.

The possible solutions mentioned above an important role is played by the combination of a shock wave between the states O and A2, followed by a simple wave starting in the state A2 and continuing to states located at the boundary between the mixed phase and the QGP [15]. The energy-density profile of this solution is shown in the lower panel of Fig. 8. For such a solution the entropy does not grow with collision energy, because the whole entropy is generated by a shock OA2 to the Chapman-Jouguet point A2 (see Fig. 10). This means that by increasing the collision energy one generates more highly compressed states which, however, have the same value of $s/\rho_B$.

Based on this solution a signal for mixed phase formation was suggested, provided that this instability of a W-kind model exists [15–17]. The important physical consequence of such an instability is a plateau in the collision-energy dependence of the total number of pions per baryon produced in a nuclear collision, i.e., $\rho_{\pi}^{tot}/\rho_B(E_{lab}) \simeq const$ [16, 17], provided that entropy is conserved during the subsequent hydrodynamic expansion. Since the total pion multiplicity consists of thermal pions and the ones which appear from decays of hadronic...
FIG. 11: Energy dependence of the entropy per baryon (circles), of the thermal pion multiplicity per baryon (squares), and of the total pion multiplicity per baryon (triangles) found at chemical freeze-out within the present HRGM. The horizontal bars are found by minimizing χ²/dof (see text). The solid curve corresponds to the RHT adiabat shown in Fig. 10.

resonances, in case of the RHT adiabat the number of thermal pions per baryon ρ_{th}^π/ρ_B should also exhibit a plateau or a plateau-like behavior with a small negative slope as a function of collision energy.

Note that the proposal of possible appearances of plateaus in the entropy per baryon and in the total pion number per baryon as functions of collision energy was strongly criticized in the literature. In Fig. 11 one can see all three plateaus at the laboratory energies E_{lab} ≃ 6.9 − 11.6 GeV, i.e., exactly where the other irregularities depicted in Figs. 3 and 5 occur. All quantities shown in Figs. 3 and 5 were found at chemical FO within the most realistic HRGM with multicomponent hard-core repulsion [6], which not only successfully describes 111 independent hadron-multiplicity ratios measured for center-of-mass energies √s_{NN} = 2.7 − 200 GeV, but also correctly reproduces the energy dependence of the Strangeness Horn with a χ²/dof ≃ 7.5/14.

It is, of course, possible that the anomalous properties of the mixed phase do not generate the mechanical instabilities for the shock transitions to this phase [15], like it was found for the Z-kind hadronic EOS [54]. Nevertheless, it was argued that even in the latter case a
plateau-like structure in the entropy per baryon, and, hence, in the thermal pion multiplicity per baryon, should be seen [15–17].

Now we are at a position to determine the parameters (individual heights for the same width) of the plateaus in the ratios $s/\rho_B$, $\rho_{th}\pi/\rho_B$ and $\rho_{tot}\pi/\rho_B$ shown in Fig. 11. We investigated a few different schemes, but came to the conclusion that a three-parameter fit is the most reliable and simple one. Since we are searching for a plateau it is clear that its height $R_A$ should be the same for a given quantity $A \in \{s/\rho_B; \rho_{th}\pi/\rho_B; \rho_{tot}\pi/\rho_B\}$. The width of all plateaus in the collision energy should also be the same, since they are generated by the same physical mechanism. Let $i_0$ denote the beginning of plateau, while $M$ denotes its width. Then one has to minimize

$$\chi^2/dof = \frac{1}{3M-3} \sum_A \sum_{i=i_0}^{i_0+M-1} \left( \frac{R_A - A_i}{\delta A_i} \right)^2$$

(4)

for all possible values of $i_0$ and $M > 1$. Here the subscript $i$ counts the data points $A_i$ to be described, whereas $\delta A_i$ denotes the error of the corresponding quantity $A_i$. We assume that the plateaus are correlated to each other, if $\chi^2/dof$ is essentially smaller than 1. Also from the practical point of view it is necessary to find the set of maximally correlated plateaus for future experiments. The height of each plateau $R_A$ is found by minimizing $\chi^2/dof$ in Eq. (4) with respect to $R_A$ and one obtains

$$R_A = \frac{\sum_{i=i_0}^{i_0+M-1} A_i}{(\delta A_i)^2} / \sum_{i=i_0}^{i_0+M-1} \frac{1}{(\delta A_i)^2}.$$  

(5)

As one can see from the table below minimal values of $\chi^2/dof < 0.2$ are reached for $M = 2$, but these are not the widest plateaus. There exist two sets for $M = 3$ with $\chi^2/dof \simeq 0.53$ for the low-energy plateaus (at $E_{lab} \simeq 6.9 - 11.6$ GeV) and with $\chi^2/dof \simeq 0.34$ for the high-energy plateaus (at $E_{lab} \simeq 30 - 40$ GeV). Precisely these sets are depicted in Fig. 11 since we believe that the high-energy set of $E_{lab} \simeq 20 - 40$ GeV with the width $M = 4$ should not be taken into account because its value of $\chi^2/dof \simeq 0.87$ is too close to 1 and, therefore, such plateaus are not strongly correlated even for these huge error bars.

IV. NEW SIGNALS OF QGP FORMATION

Here we suggest a couple of new signals indicating a boundary between the mixed phase and the QGP. First, a local minimum of the generalized specific volume $X$ at chemical FO as a function of the collision energy (see Fig. 4), signifies the existence of mechanical
TABLE I: Results of the 3-parameter fit.

|     | $M$ | $i_0$ | $R_s/\rho_B$ | $R_{\rho_B^h}/\rho_B$ | $R_{\rho_B^4}/\rho_B$ | $\chi^2$/dof |

| 3   | 7   | 18.78 | 0.835         | 2.058                   | 0.340                  |
| 4   | 6   | 17.82 | 0.779         | 1.878                   | 0.871                  |
| 5   | 5   | 16.26 | 0.648         | 1.621                   | 3.721                  |

instabilities inside the mixed phase. Note that all stable RHT adiabats of Z-kind and all unstable RHT adiabats of W-kind and the corresponding generalized shock adiabats with a QGP EOS of MIT-Bag model type [58] studied in Refs. [15–17, 51] demonstrate exactly the same behavior. The physical origin for such a behavior is that for an increase in collision energy the entropy per baryon and the temperature of the formed QGP (being a normal medium) increase as well, while the baryonic density and the baryonic chemical potential are steadily decreasing. Hence in the QGP phase the variable $X \equiv (T s/\rho_B + \mu_B)/\rho_B$ grows, if the collision energy increases. Intuitively, such a dependence seems to be true for other QGP EOS, if they correspond to a normal medium. On the other hand, the behavior of the variable $X$ inside the mixed phase with anomalous properties is opposite and it does not depend on the stability or instability of the shock transitions to this region [15,17]. On the basis of these arguments one can understand the reason why the boundary of the mixed phase and QGP corresponds to a local minimum of the $X$ variable along the RHT (shown in Fig. 10) or generalized shock adiabat and why it is also a minimum of $X$ as function of collision energy [15,17, 51].

In case of unstable shock transitions to the mixed phase, the unstable part of the mixed phase (segment $A_2B$ in Fig. 10) should be replaced by the Poisson adiabat passing through
the point A2 (the dotted curve shown in Fig. 10). Consequently, if the matter formed in a collision expands isentropically after the shock OA2 disappears, then it can be shown that for the chemical FO pattern depicted in Figs. 3 and 4, the minimum of the variable X of the initial state corresponds to a minimum of this variable at chemical FO, i.e., \( \min \{ X(E_{lab}) \} \) corresponds to \( \min \{ X^{FO}(E_{lab}) \} \). Indeed, the final states of the isentropic expansion belong to the Poisson adiabat at which \( s/\rho_B = s^{FO}V^{FO}/(2A) = \text{const} \). Here the entropy density \( s^{FO} \) and the system volume \( V^{FO} \) are taken at chemical FO, while the total number of baryons in an A+A collision is \( 2A \). At chemical FO temperatures \( T \) below 150 MeV, the hadronic EOS can be safely represented as a mixture of ideal gases of massive pions and nucleons, i.e., its pressure \( p \approx T(\rho_B + \rho_\pi) \) and energy density \( \varepsilon \approx (m_N + 3/2T)\rho_B + (m_\pi + 3/2T)\rho_\pi \) can be represented via the density of nucleons \( \rho_B \) and density of pions \( \rho_\pi \) (here \( m_N \) (\( m_\pi \)) is the nucleon (pion) mass). With the help of this EOS the variable X at chemical FO can be cast as \( X^{FO} \approx [m_N + m_\pi + 5/2T(1 + \rho_\pi/\rho_B)]s^{FO}/(2A) \). From Fig. 11 one sees that constant values of \( s/\rho_B \) in the range of \( E_{lab} = 6.9 - 11.6 \text{ GeV} \) correspond to a nearly constant ratio \( \rho_\pi/\rho_B \approx 0.5 \) and, hence, one can write \( X^{FO} \approx [m_N + m_\pi + 3.75T]V^{FO}/(2A) \) for these energies. Since for these energies the entropy density changes from 0.3 fm\(^{-3}\) to 1.944 fm\(^{-3}\), while the chemical FO temperature changes from 84 MeV to 127 MeV, it is clear that approximately one can write \( X^{FO} \approx [m_N + m_\pi + 358 \text{ MeV}]V^{FO}/(2A) \) and, hence, the value \( X^{FO}s^{FO} \approx [1536 \text{ MeV}]V^{FO}s^{FO}/(2A) = \text{const} \). A direct numerical check shows that for the chemical FO data belonging to the laboratory energy range \( E_{lab} = 6.9 - 11.6 \text{ GeV} \) one obtains \( X^{FO}s^{FO} \approx 16.9; 19.3; 23.1 \), which means that such a relation is valid with relative deviations \(-12\%\) and \(+21\%\). Note that the relation \( X^{FO}s^{FO}/[m_N + m_\pi + 3.75T] \approx \text{const} \) gives us the values 15; 16.5; 17.9, i.e., it is fulfilled with relative errors \(-9.1\%\) and \(+8.5\%\) in this energy range and these estimates validate the use of our EOS. Using these arguments, we conclude that with reasonable accuracy one can establish the relation \( X^{FO} \sim V^{FO} \sim 1/s^{FO} \) for the final states which belong to the Poisson adiabat and, therefore, the growth of entropy density (see Fig. 3) and the decrease of the variable X shown in Fig. 4 are directly related to each other.

The same treatment can be applied to higher energies. In this case one has to write \( X^{FO} \approx [m_N + m_\pi + 5/2T^{FO}(1 + \rho_\pi^{FO}/\rho_B^{FO})]s^{FO}/\rho_B^{FO}/s^{FO} \) and account for the fact that the ratios \( s^{FO}/\rho_B^{FO} \) and \( \rho_\pi^{FO}/\rho_B^{FO} \) are increasing with collision energy, while the chemical FO temperature and entropy density are almost constant for \( E_{lab} > 11.6 \text{ GeV} \) (see Fig. 3).
Hence, in this case one can write $X^{FO} \sim s^{FO}/\rho_B^{FO} \sim s^{init}/\rho_B^{init}$, where we used the entropy conservation $s^{init}/\rho_B^{init} = s^{FO}/\rho_B^{FO}$ during the expansion of the matter formed after the disappearance of the shock wave (initial matter). Therefore, for laboratory energies above 11.6 GeV the variable $X^{FO}$ should increase with the collision energy, and this is a reflection of the growth of the initial values of the $X$ variable, when the generalized shock adiabat reaches states inside the QGP.

Accounting for the above estimates, we conclude that the local minimum of $X^{FO}$ is related to the minimum of the variable $X$ on the generalized shock adiabat existing at the boundary between the mixed phase and the QGP. Moreover, the above estimates show that the minimum of the function $X^{FO}(E_{lab})$ corresponds to the minimum of the chemical freeze-out volume $V^{FO}(E_{lab})$, reported in Ref. [13] and reanalyzed recently in Ref. [5]. Thus, we find that the minimum of $V^{FO}(E_{lab})$ is generated by the unstable part of the RHT adiabat which is close to the boundary of the mixed with the QGP phase, i.e., it is another signal of QGP formation.

In the above treatment we did not consider the kinetic FO process of hydrodynamic flows and did not account for the possible entropy growth in a kinetic FO shock [56]. The reason is that the kinetic FO shock generates not more than 2% of the entropy [57] and, hence, we can safely neglect such an increase during kinetic FO and can further assume that entropy conservation holds.

Note that these conclusions were also verified numerically for the shock adiabat shown in Figs. [10] and [11] and, hence, it is appropriate to present here the employed EOS. The hadron gas pressure used in the present work accounts for the mesonic and the (anti)baryonic states which are described by the masses $m_M$, $m_B$ and by the temperature-dependent numbers of degrees of freedom [59]

$$p_H = \left[ C_B T^{AB} e^{-m_B/T} \cdot 2 \cosh(\mu/T) + C_M T^{AM} e^{-m_M/T} \right] \cdot e^{-\mu V_H/T}. \tag{6}$$

This EOS accounts for the short-range repulsion introduced via the excluded volume $V_H = \frac{4}{3} \pi R_H^3$ (with $R_H = 0.3$ fm) taken to be equal for all hadrons. With the parameters $m_M = 8$ MeV, $m_B = 800.5$ MeV, and

$$A_M = 4.95, \quad C_M = 6.90 \cdot 10^{-9} \text{ MeV}^{-1-A_M} \text{fm}^{-3},$$

$$A_B = 6.087, \quad C_B = 2.564 \cdot 10^{-9} \text{ MeV}^{-1-A_B} \text{fm}^{-3}, \tag{7}$$
such a model not only represents the mass-integrated spectrum of all hadrons, but also it rather accurately reproduces the chemical FO densities of mesons $\rho_M$ and baryons $\rho_B$ and the ratios $s/\rho_B$ and $s/\rho_M$ for chemical FO temperatures below 155 MeV \[59\]. The parameters of the center of the shock adiabat were fixed as: $p_0 = 0$, $\rho_0 = 0.159$ fm$^{-3}$ and $\varepsilon_0 = 126.5$ MeV fm$^{-3}$.

The QGP EOS is motivated by the MIT-Bag model \[58\]
\[
p_Q = A_0 T^4 + A_2 T^2 \mu^2 + A_4 \mu^4 - B ,
\]
where the constants $A_0 \simeq 2.53 \cdot 10^{-5}$ MeV$^{-3}$ fm$^{-3}$, $A_2 \simeq 1.51 \cdot 10^{-6}$ MeV$^{-3}$ fm$^{-3}$, $A_4 \simeq 1.001 \cdot 10^{-9}$ MeV$^{-3}$ fm$^{-3}$, and $B \simeq 9488$ MeV fm$^{-3}$ were found by fitting the $s/\rho_B$ chemical FO data for $E_{lab} < 50$ GeV with $s/\rho_B$ values along the RHT adiabat and by keeping the pseudocritical temperature value at zero baryonic density close to 150 MeV, in agreement with lattice QCD data \[60\].

Note that the above values of the coefficients $A_0, A_2$ and $A_4$ differ from the values $A_{L0}^T, A_{L2}^T$ and $A_{L4}^T$ obtained within lattice QCD \[60\] at vanishing baryonic chemical potential, but this difference can be attributed to the $T$ and $\mu_B$ dependence of the bag pressure
\[
B_{eff}(T, \mu_B) = B - (A_0 - A_{L0}^T)T^4 - (A_2 - A_{L2}^T)T^2 \mu^2 - (A_4 - A_{L4}^T)\mu^4,
\]
which identically generates the QGP pressure \[8\]
\[
p_Q = A_0^T T^4 + A_2^T T^2 \mu^2 + A_4^T \mu^4 - B_{eff},
\]
but with coefficients $A_{L0}^T, A_{L2}^T$ and $A_{L4}^T$. The obtained result for $B_{eff}(T, \mu_B)$ is in line with the requirements of the finite-width model \[61, 62\] of quark gluon bags.

Using the above EOS we calculated the phase diagram and constructed the RHT adiabat inside all phases. As usual, the phase transition was found from the Gibbs criterion, $p_H(T, \mu_B) = p_Q(T, \mu_B)$. The resulting RHT adiabat describes the $s/\rho_B$ chemical FO data well (see Fig. 11). The most remarkable finding is the appearance of a peak in the trace anomaly, which exists exactly at the boundary of the mixed phase and the QGP (see upper panel of Fig. 12). Comparing the trace-anomaly peak at chemical FO (see Fig. 5) and that on the RHT adiabat shown in Fig. 12 one can conclude that the respective collision energies are very close to each other. This is not a coincidence, but a natural one-to-one correspondence. A slight shift of the position of the peaks relative to each other is due to the fact that the chemical FO points are discrete while the trace-anomaly peak on the RHT adiabat is located just between two neighboring values of collision energies $E_{lab} = 8.9$ GeV ($\sqrt{s_{NN}} = 4.3$
FIG. 12: Upper panel: Energy dependence of the trace anomaly $\delta$ along the RHT adiabat of the employed EOS. The shown $\delta$-peak generates the chemical FO $\delta$-peak depicted in Fig. 5 (see text for details). Lower panel: Energy dependence of the entropy per baryon within the HRGM (circles) and the GSHM [18] (diamonds). The solid curve represents the entropy per baryon along the RHT adiabat shown in Fig. 11.

GeV) and $E_{lab} = 11.6$ GeV ($\sqrt{s_{NN}} = 4.9$ GeV). Moreover, from the fact that inside the mixed phase and inside the QGP near its border with the mixed phase the quantitative differences between the shock, Poisson, and generalized shock adiabats are very small (com-
pare, for instance, the Poisson and shock adiabats passing through the Chapman-Jouguet point $A_2$ in Fig. 10) one can safely conclude that the $\delta$-peak on the shock adiabat and on the generalized one (which consists of the Poisson and the shock adiabat) should be located at practically the same collision energy. Our numerical results support this conclusion, but the analysis of the trace anomaly along the shock adiabat is much simpler than the one for the generalized shock adiabat, which we omit here.

The large difference in the values of trace anomaly at chemical FO and at the stage of matter formation can be explained by the complicated behavior of the trace anomaly along the Poisson adiabat, but its detailed analysis is out of the scope of the present work and it will be published elsewhere. Here we would like to stress that the found relation between the trace-anomaly peaks tells one that its peak seen at chemical FO is, probably, the most direct and physically most intuitive signal for QGP formation.

At the same time there always remains the question whether the results obtained above are model independent. In particular, it is rather important to understand whether the plateaus found in the entropy per baryon can be obtained by other models of chemical FO. It is clear that the situation with the total number of charged pions per baryon is much simpler because the total number of charged pions is measured in experiment. Hence, only the model which correctly reproduces such an experimentally measured ratio should be considered to be valid. A similar situation exists for the number of thermal pions per baryon because all viable thermal models use more or less the same data on the properties of hadrons and hadronic resonances and, therefore, if two models correctly reproduce the total number of charged pions per baryon, then it is reasonable to expect that the number of thermal pions per baryon in these models will be also the same.

In order to demonstrate the model independence of the high-energy plateau in the entropy per baryon found here (see Fig. 11), we use an entirely different statistical model of chemical FO known as the generalized statistical hadronization model (GSHM) [18]. A word of caution should be added regarding the GSHM framework, because the chemical FO volumes found within the GSHM are in most cases essentially larger than the kinetic FO volumes determined by Hanbury-Brown and Twiss (HBT) measurements (for a detailed comparison of chemical and kinetic FO volumes see Ref. [14], while for a review on HBT measurements of kinetic FO volumes see Ref. [63]). In other words, within the GSHM the chemical FO occurs too late, namely only after kinetic FO, when hadrons cease to scatter elastically.
FIG. 13: Energy dependence of the total number of pions (triangles) and its derivative with respect to $E_{\text{lab}}$ (horizontal bars). The local minima at $E_{\text{lab}} \simeq 10$ GeV and $E_{\text{lab}} \simeq 30$ GeV in the derivative of the total pion number per baryon correspond to the two plateaus found in Fig. 11.

and the momentum spectra of hadrons no longer changes, while physically it should occur prior to kinetic FO. Furthermore, very recently two successful models [7, 64] were suggested, which treat the chemical FO of strange and non-strange hadrons separately. These models not only allow one to extremely well reproduce hadronic multiplicities measured in A+A collisions without any deviation of strange charge from chemical equilibrium, but they also clearly demonstrate that the apparent chemical non-equilibrium introduced long ago in Ref. [65] simply reflects the fact that the strange hadrons experience chemical FO at a different hypersurface than the non-strange ones.

Keeping these cautionary remarks in mind, we now compare the GSHM results for the entropy per baryon at chemical FO with the ones from our model. As one can see from the lower panel of Fig. 12, despite the principal differences between the HRGM [6] and the GSHM [18], the extracted values of the entropy per baryon are very close to each other. Unfortunately, the authors of Ref. [18] did not publish their error bars, but it is clear that the error bars of the GSHM should be similar to the error bars of the HRGM. In this case, as one can see from the lower panel of Fig. 12, these two different models yield, within error bars, very similar values for the entropy per baryon.

One may wonder why, despite the differences between the GSHM and the HRGM, the values for the entropy per baryon found within these models are the same within error bars.
The point is that the GSHM, like the HRGM, correctly reproduces the multiplicity ratios of many hadrons, including pions and baryons. Since at low collision energies and, hence, at low freeze-out temperatures, the entropy is simply proportional to the thermal number of pions, one should not be surprised by the agreement of the entropy per baryon between these two models. Therefore, it seems that the GSHM, despite its marked differences to our version of the HRGM, indeed also produces a plateau in the entropy per baryon at $E_{\text{lab}} = 20 - 40$ GeV. Unfortunately, the GSHM [18] does not describe the data at laboratory energies below 11 GeV.

An immediate conclusion from the comparison of the entropy per baryon for the HRGM [6] and the GSHM [18] is that, if a statistical model with or without chemical equilibrium very well reproduces all hadronic ratios, then one can safely extract from it both the entropy per baryon and the number of thermal pions per baryon. Using these quantities, one can also verify the existence of plateaus in their energy dependence with high confidence. We hope that more precise experimental data will help us to maximize this confidence in the future.

In order to give further indications for the plateaus discussed above, in the following we discuss an additional irregularity which can be obtained directly from the data. This is the behavior of the derivative of the total number of charged pions per baryon, or more precisely, the quantity $\frac{3}{2}(\rho_{\pi^+} + \rho_{\pi^-})/\rho_B$, with respect to laboratory energy, which is shown in Fig. 13. To find it we used cubic splines and then calculated the corresponding derivative. In Fig. 13 the horizontal bars correspond to the values of the derivative found in the middle between two neighboring energy points. Then the local minima at $E_{\text{lab}} \simeq 10$ GeV and $E_{\text{lab}} \simeq 30$ GeV in the derivative of the total pion number per baryon correspond to the two plateaus found above.

It is necessary to make a remark on the origin of the high-energy plateau. The main question is whether such a plateau provides evidence for a putative mixed phase, with an associated instability of the shock adiabat. A close inspection of Figs. 3, 4, and 5 reveals that at RHIC energy $\sqrt{s_{NN}} = 9.2$ GeV (or $E_{\text{lab}} \simeq 44$ GeV) [32], there may be a hint of irregularities similar to the ones associated with the low-energy plateaus, but, unfortunately, their small amplitude compared to the neighboring points and very large error bars at the moment do not allow us to safely interpret them as clear signals of some instability or another mixed phase. However, the absence of a reliable dynamic approach with a phase transition, which
can be used to model the collision process at these energies, does not allow us to rule out the possibility of another phase transition.

Therefore, at present we see the following three possibilities regarding the high-energy plateaus. The first possibility is that the high-energy plateaus are, in fact, quasiplateaus which are similar to the ones that were found for a pure QGP EOS in the case of Z-kind models [16]. They are not associated with another phase transition and with another mixed phase instability, but may appear at high energy density due to specific features of the bag model EOS used for the QGP. In this case only the low-energy plateaus correspond to the quark-gluon-hadron mixed phase.

The second possibility is similar to the previous one in respect that the quasiplateaus at $E_{\text{lab}} \simeq 30 - 44$ GeV do not correspond to a second phase transition which, however, exists at much higher energies. For instance, from the acoustic scaling of the elliptic flow the PHENIX Collaboration concluded that the phase transition or critical endpoint may exist at center-of-mass energies $\sqrt{s_{NN}} \simeq 30 - 40$ GeV [66, 67]. It is clear that the second possibility may correspond to a tricritical QCD phase diagram endpoint, if both phase transition curves match at this point, or there may exist two critical endpoints, if the phase transition curves do not intersect each other.

Finally, only in the third case, if both sets of plateaus correspond to instabilities existing inside two phase transition regions, the traditional irregularities [1–3] may reflect the second phase transition. But even in this case it is unclear whether the onset of deconfinement begins exactly at $\sqrt{s_{NN}} \simeq 7.6$ GeV ($E_{\text{lab}} \simeq 30$ GeV) as it is suggested in Ref. [4] or whether it can appear at $\sqrt{s_{NN}} \simeq 10$ GeV as suggested in the work on quarkyonic matter [68]. At the moment it is absolutely unclear whether the second phase transition is a deconfinement or a chiral symmetry restoring transition. Moreover, it is an open question whether this is a second-order phase transition, a first-order one, or a cross-over. From the current state of the art one can speculate that the local minimum of $X(\sqrt{s_{NN}})$ and the small peak of the trace anomaly $\delta$ seen at $\sqrt{s_{NN}} \simeq 9.2$ GeV could, probably, signal a very weak first-order phase transition or a second-order one, but the error bars of the quantities measured at this energy range are very large and, hence, to make a more definite conclusion we need about ten more data points and an experimental accuracy that is one order of magnitude better.
V. CONCLUSIONS

In this work we have presented remarkable irregularities at chemical FO elucidated via a high-quality fit of experimental particle ratios obtained by the advanced version of the hadron resonance gas model. The fit quality achieved, \( \chi^2/dof \simeq 1.16 \), lends our results high confidence. Among these irregularities we observed a dramatic jump of the effective number of degrees of freedom at center-of-mass collision energies \( \sqrt{s_{NN}} = 4.3 - 4.9 \) GeV. At \( \sqrt{s_{NN}} = 4.9 \) GeV we also found a local minimum of the generalized specific volume \( X^{FO}(\sqrt{s_{NN}}) \) and a sharp peak of the trace anomaly \( \delta(\sqrt{s_{NN}}) \).

Furthermore, at chemical FO we found two sets of plateaus in the collision-energy dependence of the entropy per baryon, and of the total and the thermal numbers of pions per baryon, which were predicted a long time ago [15–17]. We discussed in some detail the generalized shock-adiabat model for low-energy central nuclear collisions and argued that the plateaus and the minimum of \( X^{FO}(\sqrt{s_{NN}}) \) found at low collision energies are generated by the RHT-adiabat instabilities existing at the boundary between the mixed phase and the QGP. A numerical calculation of the RHT adiabat for a realistic EOS of the hadronic phase allowed us to reproduce the \( s/\rho_B \) plateau and to fix the parameters of the QGP EOS. Moreover, the trace anomaly \( \delta \) calculated along the RHT adiabat exhibits a sharp peak at the boundary of QGP and mixed phase, which is located at center-of-mass collision energies \( \sqrt{s_{NN}} \simeq 4.46 \) GeV. Our numerical analysis shows a one-to-one correspondence between the trace-anomaly peaks found on the RHT adiabat and at chemical FO. Therefore, it is quite possible that the trace-anomaly peak found at chemical FO in combination with other irregularities provide clear evidence of the phase transition to the QGP in nucleus-nucleus collisions.

Also, at chemical FO we found a second set of plateaus at \( E_{lab} \simeq 30 - 44 \) GeV, which, however, does not correspond to a phase transition or to the discussed instabilities. Since the generalized shock-adiabat model is not applicable at this energy range we cannot make definite conclusions about the origin of this set of plateaus. However, the most remarkable fact is that a similar plateau in the collision-energy dependence of the entropy per baryon occurs in the same energy range within an entirely different model known as GSHM [18]. This example demonstrates that any statistical model of chemical FO which correctly reproduces the multiplicities of the most abundant hadrons such as pions and baryons should be able
to generate similar values of the entropy per baryon because at chemical FO the main
collection to the entropy is provided by pions. Therefore, at chemical FO we may expect
a model-independent behavior of the entropy per baryon as function of collision energy.

In order to make more definite conclusions about the plateaus found at laboratory energies 30\textendash{}44 GeV one needs more precise data measured in steps of $E_{lab}$ of about 100-200 MeV and
a more realistic model of heavy-ion collisions in this range of collision energies. However, now it is already clear that, if an additional phase transition indeed exists at laboratory
ergies 30 \textendash{} 44 GeV, then both sets of plateaus found here may be considered as the first
evidence of two phase transitions in QCD.

Acknowledgments. The authors are thankful to E.V. Shuryak and I. P. Yakimenko for
important comments. K.A.B., D.R.O., A.I.I., V.V.S., and G.M.Z. acknowledge support from
