ABSTRACT

Context. Observations indicate that wind can be generated in hot accretion flow. Wind generated from weakly magnetized accretion flow has been studied. However, the properties of wind generated from strongly magnetized hot accretion flow have not been studied.

Aims. In this paper, we study the properties of wind generated from both weakly and strongly magnetized accretion flow. We focus on how the magnetic field strength affects the wind properties.

Methods. We solve steady-state two-dimensional magnetohydrodynamic equations of black hole accretion in the presence of a large-scale magnetic field. We assume self-similarity in radial direction. The magnetic field is assumed to be evenly symmetric with the equatorial plane.

Results. We find that wind exists in both weakly and strongly magnetized accretion flows. When the magnetic field is weak (magnetic pressure is more than two orders of magnitude smaller than gas pressure), wind is driven by gas pressure gradient and centrifugal forces. When the magnetic field is strong (magnetic pressure is slightly smaller than gas pressure), wind is driven by gas pressure gradient and magnetic pressure gradient forces. The power of wind in the strongly magnetized case is just slightly larger than that in the weakly magnetized case. The power of wind lies in a range $P_w \sim 10^{-4} \sim 10^3 M_{\odot} c^2$, with $M_{\odot}$ and $c$ being mass inflow rate and speed of light, respectively. The possible role of wind in active galactic nuclei feedback is briefly discussed.

Key words. accretion, accretion disks

1. Introduction

Advection-dominated accretion flow (ADAF) can have either a low or high accretion rate. When the accretion rate is much larger than the Eddington rate, due to large optical depth, the photons are trapped in the flow and advected to the black hole. The high accretion rate ADAF is called slim disk (Abramowicz et al. 1988). When the accretion rate is significantly smaller than the Eddington rate, the flow density is very low. In this case, the radiation is not important. The flow temperature is close to the Virial temperature. The low accretion rate ADAF is called hot accretion flow.

The hot accretion flow model has been popular since the 1990s (Narayan & Yi 1994, 1995; Abramowicz et al. 1995; Kato et al. 1998; Narayan et al. 1998). In low-luminosity active galactic nuclei (LLAGNs), the black hole is believed to accrete matter in the hot accretion flow mode (e.g., Ho 2008; Antonucci 2012; Done 2014). In hard and quiescent states of black hole X-ray binaries, the black hole also accretes matter in the hot accretion flow mode (e.g., Esin et al. 1997; Fender et al. 2004; Zdziarski & Gierliński 2004; Narayan 2005; Remillard & McClintock 2006; Narayan & McClintock 2008; Belloni 2010; Wu et al. 2013; Yuan & Narayan 2014). In recent years, lots of numerical simulations have been performed to study the properties of hot accretion flow (e.g., Stone et al. 1999; Igumenshchev & Abramowicz 1999, 2000; Hawley et al. 2001; Machida et al. 2001; Stone & Pringle 2001; Hawley & Balbus 2002; De Villiers et al. 2003; Penn et al. 2003; Beckwith et al. 2008; Pang et al. 2011; Tchekhovskoy et al. 2011; Tchekhovskoy & McKinney 2012; Yuan et al. 2012a,b; McKinney et al. 2012; Narayan et al. 2012; Li et al. 2013; Sadowski et al. 2013; Mościbrodzka et al. 2014).

In recent years, there are observations of both LLAGNs (e.g., Crenshaw & Kraemer 2012; Tombesi et al. 2010a, 2014; Wang et al. 2013; Cheung et al. 2016) and the hard state of black hole X-ray binaries (Homan et al. 2016). These observations indicate that winds can be generated from hot accretion flow. The origin of wind in weakly magnetized hot accretion flow has been studied by numerical simulation (Yuan et al. 2015). In Yuan et al. (2015), magnetic pressure was found to be smaller than gas pressure by a factor of several tens. They found that wind is driven by the combination of gas pressure gradient, magnetic pressure gradient, and centrifugal forces. The origin of wind has also been studied by analytical works. In these works, the effects of magnetic field (Lorentz force) are neglected (e.g., Begelman 2012; Gu 2015).

It is very important to study wind properties for the following reasons. First, wind is an important ingredient of accretion physics. If wind is present, the mass accretion rate can no longer be a constant with radius. The change of the mass accretion rate profile changes the gas density profile. The change of density profile can change the spectrum of a black hole.
accretion system (e.g., Quataert & Narayan 1999; Yuan et al. 2003). Second, there is consensus that active galactic nuclei (AGN) feedback can affect the evolution of their host galaxies significantly (e.g., Ciotti & Ostriker 1997, 2001, 2007; Proga et al. 2000; Novak et al. 2011; Gan et al. 2014, 2017; King & Pounds 2015; Ciotti et al. 2017). Wind can push away the gas at sub-parsec and parsec scales. Consequently, the feeding rate of the central black hole can be significantly affected. The change of gas properties at parsec scale can also affect the star formation rate (e.g., Ciotti et al. 2017). Before studying the feedback by AGN wind, we should study the properties of wind.

Both cold disk (Shakura & Sunyaev 1973) and hot accretion flow can produce wind. Luminous AGNs are powered by a standard thin disk (Shakura & Sunyaev 1973). Blueshifted absorption lines of highly ionized iron are frequently observed in luminous AGNs. The large blueshift of lines indicates that wind has a velocity of 0.1–0.3c, with c being the speed of light. Such high velocity wind is called ultra-fast outflows (UFOs; Tombesi et al. 2010b, 2011). UFOs are generated inside a 100 Schwarzschild radius. The power of UFOs can be $5 \times 10^{36}$ L$_{Edd}$, with $L_{Edd}$ being Eddington luminosity (Nomura & Ohsuga 2017). The status of the study of wind from hot accretion flows is quite different from the case of cold accretion disks. In this case, the observational data is much less compared to the case of cold disk. This is mainly because the gas in the wind from a hot accretion flow is very hot thus generally fully ionized. So it is very difficult to detect by the usual absorption-line spectroscopy. However, in recent years, we have gradually accumulated more observational evidence for wind from low-luminosity sources in which we believe that a hot accretion flow is operating (e.g., Crenshaw & Kraemer 2012; Tombesi et al. 2010a, 2014; Wang et al. 2013; Cheung et al. 2016; Homan et al. 2016). The properties of wind from hot accretion flow are mainly studied by numerical simulations. Simulation works find that the poloidal velocity of wind is approximately $0.2v_{\infty}$, with $v_{\infty}$ being the Keplerian velocity of the location where wind is generated. The power of wind is $1/1000$ $M\dot{c}^2$, with $M$ being the black hole accretion rate (Yuan et al. 2015).

We define plasma $\beta = p/p_{\text{mag}}$, where $p$ and $p_{\text{mag}}$ are the gas pressure and the magnetic pressure, respectively. Numerical simulations found that hot accretion flow can have either large or small $\beta$. When $\beta$ is large ($\beta \geq 10$), magnetic pressure is much smaller than gas pressure; accretion flow is weakly magnetized. In this case, angular momentum is transferred by Maxwell stress associated with magnetohydrodynamic (MHD) turbulence driven by magneto-rotational instability (MRI; Balbus & Hawley 1998). The weakly magnetized hot accretion flow is called “standard and normal evolution” (SANE) model (Narayan et al. 2012). When $\beta$ is small (e.g., $\beta \leq 10$), the magnetic pressure becomes comparable to the gas pressure. In this case, the magnetic field is too strong so that MHD turbulence is suppressed. Angular momentum is transferred by a strong, ordered large-scale magnetic field (Stone & Norman 1994; Narayan et al. 2012; McKinney et al. 2012; Tchekhovskoy & McKinney 2012). The strongly magnetized accretion flow is called the “magnetically arrested disk” (MAD; e.g., Narayan et al. 2012). For the MAD, the accretion rate is strongly suppressed by the strong magnetic field.

The detailed properties of the wind in the SANE model have been investigated by Yuan et al. (2012b; see also Yuan et al. 2015). However, the properties of wind in strongly magnetized hot accretion flows have not been studied. In Yuan et al. (2015), it is found that the wind is driven by the combination of magnetic pressure gradient, gas pressure gradient, and centrifugal forces. Therefore, the strength of the magnetic field could be an important factor in determining the properties of wind. In this paper, we study how the wind properties change with the changing of magnetic field strength. We study both weakly and strongly magnetized hot accretion flows. We obtain the two-dimensional axisymmetric steady solution of hot accretion flow in the presence of magnetic field. We assume radial self-similarity as in many previous works.

Analytical works assuming radial self-similarity have been done by many authors. In the one-dimensional solution, wind is usually assumed to be present (e.g., Blandford & Begelman 1999; Akizuki & Fukue 2006; Abbassi et al. 2008; Zhang & Dai 2008; Bu et al. 2009). Wind has been automatically found in two-dimensional solutions (e.g., Xu & Chen 1997; Blandford & Begelman 2004; Xue & Wang 2005; Tanaka & Menou 2006; Jiao & Wu 2011; Mosallanezhad et al. 2014; Gu 2015; Samadi & Abbassi 2016). However, we note here that in all above-mentioned works, magnetic field is not taken into account. It is well known that magnetic field plays a significant role in the dynamics of accretion flow. Therefore, it is necessary to obtain the accretion solutions in the presence of a magnetic field. In this paper, we will study how the wind properties change with the changing of magnetic field strength.

This paper is organized as follows. In Sect. 2, we introduce the basic MHD equations and assumptions. The detailed descriptions of numerical solutions are described in Sect. 3. In Sect. 4, we provide a summary and briefly discuss the implications of our results.

2. Basic equations

In this section, we derive the basic equations for steady-state, axisymmetric hot accretion flows incorporating magnetic fields. We adopt spherical coordinates $(r, \theta, \phi)$. General-relativistic effects are neglected and we use Newtonian potential $\psi = -GM/r$, where $G$ is the gravitational constant and $M$ is the mass of the central black hole. The basic resistive MHD equations of hot accretion flow can be described as

$$\frac{\partial \rho}{\partial t} + \nabla \cdot (\rho \mathbf{v}) = 0, \quad (1)$$

$$\rho \left[ \frac{\partial \mathbf{v}}{\partial t} + (\mathbf{v} \cdot \nabla) \mathbf{v} \right] = -\rho \nabla \psi - \nabla p + \nabla \cdot \mathbf{T} + \frac{\mathbf{J} \times \mathbf{B}}{c}, \quad (2)$$

$$\frac{\partial e}{\partial t} + \nabla \cdot (e \mathbf{v}) + p \nabla \cdot \mathbf{v} = q^r - q_{\text{rad}}, \equiv f q^+, \quad (3)$$

$$\frac{\partial \mathbf{B}}{\partial t} = \nabla \times \left( \mathbf{v} \times \mathbf{B} - \frac{4\pi}{c^2} n \mathbf{J} \right), \quad (4)$$

$$\nabla \cdot \mathbf{B} = 0, \quad (5)$$

where $\rho$ is the density, $\mathbf{v} = (v_r, v_\theta, v_\phi)$ is the velocity, $p$ is the gas pressure, $\mathbf{T}$ is the viscous stress tensor, $J = (c/4\pi)\nabla \times \mathbf{B}$ is the current density, $\mathbf{B} = (B_r, B_\theta, B_\phi)$ is the magnetic field, and $e$ is the internal energy density of the gas. We adopt an adiabatic equation of state, $p = (\gamma - 1)e$, where $\gamma$ is the adiabatic index of the gas which is set to 5/3 here. In the energy Eq. (3), $q^+$ is the heating rate, $q_{\text{rad}}$ is the radiative cooling rate, and $f$ represents the advection factor describing the fraction of the heating energy
stored in the gas and advected towards the central black hole. In the induction Eq. (4), \( \eta = c^2/(4\pi \sigma B) \) is the magnetic diffusivity, where \( \sigma B \) denotes the electric conductivity. We include the dissipation term in Eq. (4) in order to obtain a steady solution. If the dissipation term is neglected, there will be no steady-state solution due to the continuous accumulation of magnetic flux.

Numerical simulation found that the azimuthal component of viscosity is much larger than other components (Stone & Pringle 2001). Therefore in this study we set the viscous tensor to have only the azimuthal component,

\[
T_{\phi \phi} = \mu \frac{\partial}{\partial r} \left( \frac{v_\phi}{r} \right),
\]

where \( \mu \equiv \rho \nu \) is the dynamical viscosity coefficient and \( \nu \) is the kinematic viscosity. We model viscosity with the standard \( \alpha \)-prescription (Shakura & Sunyaev 1973), where the kinematic viscosity of the viscosity \( \nu \) can be expressed as

\[
\nu = \frac{\alpha \rho}{\Omega_k}.
\]

Here, \( \Omega_k = (GM/r^3)^{1/2} \) is the Keplerian angular velocity and \( \alpha \) is a constant viscosity parameter. We assume that both viscosity and magnetic dissipation can heat the gas. Therefore, the heating rate \( q^+ \) will be decomposed into two terms,

\[
q^+ = q_{\text{vis}} + q_{\text{res}},
\]

with

\[
q_{\text{vis}} = T_{\phi r} \frac{\partial}{\partial r} \left( \frac{v_\phi}{r} \right),
\]

\[
q_{\text{res}} = 4\pi \eta \mu^2 J^2,
\]

where \( q_{\text{vis}} \) and \( q_{\text{res}} \) are the viscous heating and the magnetic field dissipation heating, respectively. We set the magnetic diffusivity to be \( \eta = \eta_0 (\rho/\rho_k) \) to satisfy the radially self-similar assumption.

Global and local numerical MHD simulations of black hole accretion disks found that the magnetic field can be decomposed into an ordered large-scale component and a turbulent component (e.g., Machida et al. 2006; Johansen & Levin 2008; Bai & Stone 2013; Zhu & Stone 2018). Both large-scale and turbulent components can transfer angular momentum. The dissipation of magnetic field can heat the gas in this paper, the magnetic field \( B \) in Eqs. (2), (4), and (5) represents the large-scale ordered component. The term \( q_{\text{res}} \) represents the heating by dissipation of the large-scale component of the magnetic field. The angular momentum transfer by a small-scale turbulent magnetic field is modeled by the viscous force \( \nabla \cdot \mathbf{T} \) in Eq. (2). The dissipation heating of gas by a small-scale turbulent magnetic field is modeled by the viscous heating \( q_{\text{vis}} \).

The magnetic field configuration is assumed to be evenly symmetric about the equatorial plane (e.g., Blandford & Payne 1982; Lovelace et al. 1994; Cao 2011; Li & Begelman 2014):

\[
B_r(r, \theta) = -B_r(r, \pi - \theta),
\]

\[
B_\theta(r, \theta) = +B_\theta(r, \pi - \theta),
\]

\[
B_\phi(r, \theta) = -B_\phi(r, \pi - \theta).
\]

The radial component of the magnetic field can be stretched into the azimuthal component due to the shear of accretion flow. Thus, the radial and azimuthal components of the magnetic field have opposite signs. In this paper, we study the region above the equatorial plane. The radial component of the magnetic field is set to be positive (\( B_r > 0 \)). Accordingly, the azimuthal component of the magnetic field is negative (\( B_\phi < 0 \)).

We assume steady-state and axisymmetric flow (\( \partial \phi/\partial t = \partial (\partial \theta/\partial t) = 0 \)), and adopt a self-similar approximation to remove the radial dependence of physical quantities. In terms of a fiducial radial distance, \( r_0 \), the self-similar solutions are defined as a power-law form of \( r/r_0 \).

The MHD equations of the flow admit the following radial scaling relations for the variables,

\[
v(r, \theta) = \sqrt{\frac{GM}{r_0}} \left( \frac{r}{r_0} \right)^{-1/2} v(\theta),
\]

\[
\rho(r, \theta) = \frac{M}{r_0^3} \left( \frac{r}{r_0} \right)^{-\alpha} \rho(\theta),
\]

\[
p(r, \theta) = \frac{GM^2}{r_0^4} \left( \frac{r}{r_0} \right)^{-\alpha-1} p(\theta),
\]

\[
B(r, \theta) = \sqrt{\frac{GM^2}{r_0^4} \left( \frac{r}{r_0} \right)^{(n/2)-(1/2)}} b(\theta).
\]

Numerical simulations of hot accretion flow show that the radial profile of density can be described as a power-law function of \( r \) as \( \rho \propto r^{-n} \), with \( 0.5 < n < 1 \) (e.g., Stone et al. 1999; Yuan et al. 2012a). Therefore, in this paper we assume that \( \rho \propto r^{-n} \). According to the power-law function of density, the power-law function of magnetic field and gas pressure are set to satisfy the radially self-similar condition. In this paper, we set \( n = 0.85 \). We have done some tests with other values of \( n \). We found that if \( n \) is slightly changed, the results will not change much.

Under the above-mentioned assumptions, Eqs. (1)–(5) can be simplified as

\[
\rho \left[ \frac{3}{2} - 3 n \right] v_r + v_\theta \cot \theta + \frac{dv_\theta}{d\theta} + \frac{\eta_0}{\rho_0} = 0,
\]

\[
\rho \left[ -\frac{1}{2} v_r^2 + v_\theta \frac{dv_r}{dr} - v_\theta^2 - v_\phi^2 \right] = -\rho + (n + 1)p + \frac{1}{4\pi} (j_\phi b_\phi - j_\theta b_\theta),
\]

\[
\rho \left[ \frac{1}{2} v_r v_\theta + v_\theta \frac{dv_\theta}{d\theta} - v_\phi^2 \cot \theta \right] = -\frac{dp}{d\theta} + \frac{1}{4\pi} (j_\phi b_\phi - j_\theta b_\theta),
\]

\[
\rho \left[ \frac{1}{2} v_r v_\theta + v_\theta \frac{dv_\theta}{d\theta} + v_\phi v_\phi \cot \theta \right] = \frac{3}{2} (n - 2) \alpha v_\phi p + \frac{1}{4\pi} (j_\phi b_\phi - j_\theta b_\theta),
\]

\[
\left( \frac{3}{2} - n - 1 \right) v_r p + \nu_0 \frac{dp}{d\theta} + \gamma p \left[ \frac{dv_\theta}{d\theta} + v_\theta \cot \theta \right] = f(\gamma - 1) \frac{9}{4} \alpha \nu v_\phi^2 + \eta \frac{1}{4\pi} (j_\phi^2 + j_\theta^2 + j_\phi^2),
\]
3. Results

Equations (18)–(24) are solved numerically. We set $B_t$ and $B_\phi$ to be null at the equatorial plane. Above the equatorial plane, we set $B_t$ to be positive; $B_\phi$ is generated by the shear of the flow and should be negative. The MHD equations are integrated from $\theta = \pi/2$ toward the rotational axis ($\theta = 0$). We find that $B_\phi$ becomes positive at an angle $\theta_1$ near the rotation axis. We stop integration at $\theta_1$. We believe the solution in the region of $\theta_1 < \theta < \pi/2$ is still physical.\(^1\) The reasons are as follows. First, the solutions satisfy boundary conditions at $\theta = \pi/2$. Second, the physical quantities at $\theta_1$ are physical. Therefore, we can reasonably treat these values as boundary conditions at $\theta_1$. In fact, in Mosallanezhad et al. (2016), we also study the properties of accretion flow by assuming radial self-similarity. It is shown that the main properties of the solutions obtained in this way are in good agreement with those obtained in Yuan et al. (2015) from numerical simulations.

The parameters we adopt are $\alpha = \eta_1 = 0.1$. Numerical simulations of hot accretion flow show that the radial profile of density can be described as a power-law function of $r$ as $\rho \propto r^{-n}$, with $0.5 < n < 1$ (e.g., Stone et al. 1999; Yuan et al. 2012a). In this paper, we set $n = 0.85$. We also assume that radiation is not important and set the advection factor $f = 1$. In this paper, we have three models. In model A, the plasma beta at the equatorial plane is $\beta_0 = 250$. In models B and C, $\beta_0 = 50$ and 5, respectively. The magnetic field is strongest in model C. The magnetic field strength in model B is moderate. In model A, the magnetic field is the weakest.

Figure 1 plots the angular profiles of physical quantities. The blue, red, and green lines are for $\beta_0 = 250$ (model A), 50 (model B), and 5 (model C), respectively. It is clear that at the region close to the equatorial plane $\theta > 40^\circ$, the radial velocity is negative and gas flows toward the black hole. The region $\theta > 40^\circ$ is the inflowing region. In the region $\theta < 40^\circ$, the radial velocity is positive. The region $\theta < 40^\circ$ is the wind region. This result is fully consistent with that obtained by simulations (Yuan et al. 2015; see also Narayan et al. 2012; Sadowski et al. 2013). In those works, it is found that inflow is present around the equatorial plane while wind is present in the polar region.

The azimuthal velocity (see Fig. 1) in the highly magnetized case ($\beta_0 = 5$) is significantly smaller than those in weakly magnetized cases ($\beta_0 = 50$ and 250). The reason is as follows. In highly magnetized accretion flow, Maxwell stress is large. Angular momentum can be transferred outward very efficiently. Therefore, the specific angular momentum (or equivalently azimuthal velocity) of highly magnetized accretion flows is much smaller. Numerical simulations also find that the specific angular momentum of gas in the MAD model is significantly smaller than that in the SANE model (Narayan et al. 2012; Tchekhovskoy & McKinney 2012; McKinney et al. 2012).

The quantities $v_\theta$ and $v_\phi$ increase with decreasing $\theta$. This is consistent with what was found in Jiao & Wu (2011). In the wind region ($\theta < 40^\circ$), we find that the poloidal velocity

\[
\left( v_p = \sqrt{v_\theta^2 + v_\phi^2} \right)
\]

of wind in the strongly magnetized flow is larger than that in the weakly magnetized flow (see Fig. 1). In order to study the reason for the difference of poloidal velocity in different models, we calculate the forces at the wind region. Figure 2 shows the result. The left and right panels are for models A and C, respectively. In the weakly magnetized case (model A), the dominant driving forces for wind are the centrifugal force and the gradient of the gas pressure. In the strongly magnetized case (model C), the centrifugal force is much smaller due to the low rotational velocity in this model (see left panel of the second row of Fig. 1). The magnetic pressure gradient force in model C is much stronger than that in model A. The gas pressure gradient force is larger in model C than in model A. The total force in model C is larger than in model A. Therefore, the poloidal velocity of wind in model C is greatest. We note that the poloidal velocity of wind in model C is just slightly larger than that in models A and B.

From Fig. 1, we can see that from the equatorial plane to the rotation axis, the density and pressure decrease. From the bottom right panel of Fig. 1, we see that the temperature (or sound speed) in model C is slightly higher than that in models A and B. The temperature of accretion flow depends on heating. In this paper, we have both viscous and magnetic dissipation heating. In viscous heating, $q_{\text{vis}} \propto (v_P r)^2$. In magnetic dissipation heating, $q_{\text{dis}} \propto B^2$. In model C, the azimuthal velocity is much smaller than that in models A and B. Therefore, the viscous heating in model C is much smaller than in model A and B. However, the magnetic dissipation rate in model C is much bigger than that in models A and B because the magnetic field is much stronger in model C. The total heating rate per particle in model C is much bigger than in models A and B. Quantitatively, we find that the

\[\frac{n}{2} \left( v_\theta b_\theta - v_\phi b_\phi \right) + v_\phi \frac{db_\theta}{d\theta} + b_\theta \frac{dv_\phi}{d\theta} - v_\theta \frac{db_\phi}{d\theta} - b_\phi \frac{dv_\theta}{d\theta} + \frac{n}{2} \eta_j f_j + \eta_{j} j_{\theta} \frac{d\eta_{j}}{d\theta} + j_{\phi} \frac{dj_{\phi}}{d\theta} = 0. \tag{23}\]

\[
\frac{db_\theta}{d\theta} = \frac{1}{2} (n-3) b_\theta + b_\phi \cot \theta = 0, \tag{24}\]

where,

\[
j_{\theta} = \frac{db_\phi}{d\theta} + b_\phi \cot \theta, \tag{25}\]

\[
j_{\phi} = \frac{1}{2} (n-1) b_\theta - \frac{db_\theta}{d\theta}. \tag{26}\]

The above differential equations consist of eight variables: $v_\theta(\theta), v_\phi(\theta), \rho(\theta), \rho(\theta), p(\theta), b_\theta(\theta), b_\phi(\theta)$, and $b_\phi(\theta)$. By assuming even symmetry for the accretion flow about the equatorial plane, the boundary conditions require,

\[
\frac{dv_\theta}{d\theta} = \frac{dv_\phi}{d\theta} = \frac{dp}{d\theta} = \frac{db_\theta}{d\theta} = \frac{db_\phi}{d\theta} = \frac{db_r}{d\theta} = 0. \tag{28}\]

We set the density at the equatorial plane $\rho(\pi/2) = 1$. Also, the magnetic field strength is set to,

\[
\beta_0 = \frac{8 \pi \rho(n/2)}{b_\phi^2(n/2)}. \tag{29}\]

---

\(^1\) Two-dimensional results found in Jiao & Wu (2011) are similar in the sense that they also had to stop in their integration at a certain $\theta > 0$. 

A&A 615, A35 (2018)}
Fig. 1. Angular profiles of variables. The blue, red, and green lines are for $\beta_0 = 250$, 50, and 5, respectively. The ratio of gas pressure to magnetic pressure at the equatorial plane is denoted by $\beta_0$. **Top-left panel**: radial velocity. **Top-right panel**: $v_{\theta}$. **Left panel** of the second row: azimuthal velocity. **Right panel** of the second row: poloidal velocity ($v_p = \sqrt{v_{\theta}^2 + v_r^2}$). **Left panel** of the third row: density. **Right panel** of the third row: gas pressure. **Bottom-left panel**: $\beta$. In the **bottom-right panel**, the solid lines are for sound speed and the dashed lines are for Alfvén speed. The **top-left panel** shows that the radial velocity changes its sign at $\theta \sim 40^\circ$.

The total heating rate in model C is larger than in models A and B by a factor of $\sim 1.5$. Therefore, the temperature of gas in model C is highest. The Bernoulli parameter is usually used to judge whether wind can escape to infinity. In magnetized accretion flow, the Bernoulli parameter is defined as (Zhu & Stone 2018; A35, page 5 of 8)
Fig. 2. Force analysis at wind region to show driving mechanism of wind. The left and right panels are for models A and C, respectively. The length of the arrows schematically denotes the magnitude of the forces. $F_g$: gravitational force; $F_c$: centrifugal force; $F_{\text{total}}$: the total force.

The numerical simulation result of the SANE model obtained by Yuan et al. (2012b) showed that $Be(r)/v_K^2(r) \approx (0.1–0.2)$. Therefore, our present result is in good agreement with that obtained by numerical simulations.

We also calculate the kinetic and thermal energy carried by the wind as

$$P_k(r) = 2\pi r^2 \int_{0}^{90} \rho \max(v_r, 0) \sin \theta d\theta,$$  

$$P_{\text{th}}(r) = 4\pi r^2 \int_{0}^{90} \rho e \max(v_r, 0) \sin \theta d\theta.$$  

The Poynting energy flux is

$$P_B(r) = 4\pi r^2 \int_{0}^{90} S_r \max(v_r, 0) \sin \theta d\theta.$$  

The radial component of Poynting flux $S_r$ is defined as (Igumenshchev 2008)

$$S_r = \frac{B_r^2}{4\pi} - \frac{B \cdot \nabla \times B}{4\pi}.$$  

In this paper, the total power of wind is calculated as

$$P_W = P_k + P_{\text{th}} + P_B.$$  

We assume that the Poynting flux is part of the energy flux of wind. This is because it is believed that the Poynting flux will be converted into the kinetic power of wind (Spruit 2010; Li & Cao 2010). Figure 4 plots power carried by the wind. We have calculated the mass flux of wind in models A, B, and C. We find that in model C the mass flux of wind is slightly larger than in models A and B. In model C the mass flux of wind is just slightly increased by a factor of 0.03 compared to that in model A. The density and velocity of wind (see Fig. 1) do not change much from models A–C. Therefore, the mass flux of wind in the three models does not differ much. The thermal power in model C is slightly larger than in models A and B. This is because the temperature and wind mass flux in model C are larger than in models A and B. The Poynting flux in model C is three times that in model A. The reason is that the magnetic field in model C is much larger than that in model A. Finally, the kinetic power also increases by a factor of two from model A to model B. The total power in model C is 1.6 times that in model A.

\[ \beta_0 = 2.5a2 \]

\[ \beta_0 = 5.0 \]
Fig. 4. Power carried by wind in units of $M_{\text{in}} c^2$. The red and blue lines correspond to thermal and kinetic powers carried by wind, respectively. The green line shows Poynting flux. The black line shows the total power.

4. Summary and discussion

In this paper, we solve two-dimensional MHD equations of hot accretion flow incorporating an evenly symmetric magnetic field. In order to simplify the equations, we assume radial self-similarity. We find that wind is present at $\theta < 40^\circ$, while inflow is present around the equatorial plane. This structure is the same as that obtained in previous numerical simulation works (e.g., Yuan et al. 2012b, 2015; Narayan et al. 2012; Sadowski et al. 2013).

We focus on how the wind properties change with magnetic field strength. We find that when the magnetic pressure is more than two orders of magnitude smaller than the gas pressure ($\beta > 100$; weakly magnetized flow), wind is driven by the combination of the gas pressure gradient and the centrifugal forces. However, when the magnetic field is strong ($\beta < 10$), wind is driven by the combination of the gas pressure gradient and the magnetic pressure gradient forces. We find that the Bernoulli parameter does not change much with the change of magnetic field strength. The Bernoulli parameter of wind from both weakly and strongly magnetized accretion flow is about $Be \sim 0.16 v_K^2$. We have also calculated the power carried by wind. We find that the power of wind in strongly magnetized flows is around 1.6 times that of wind in weakly magnetized flows.

The power of wind is in the range $10^{-4} - 10^{-3} M_{\text{in}} c^2$. If wind is generated close to the black hole, then $M_{\text{in}}$ is roughly equal to the accretion rate onto the black hole. In numerical simulations studying the evolution of galaxies (e.g., Ciotti et al. 2010; Ostriker et al. 2010; Gaspari et al. 2012), it is found that AGN wind can interact with the intercluster medium and heat the intercluster medium. The heating by AGN wind is useful to prevent rapid cooling of the gas (i.e., the cooling flow problem). In order to be consistent with observations, the power of AGN wind should be in the range $P_w \sim 10^{-4} - 10^{-3} M_{\text{BH}} c^2$. Thus, wind generated by hot accretion flow may play a role in solving the rapid cooling problem of the intercluster medium when the AGN is in hot accretion mode.
