While spin textures in materials exhibiting zero net magnetization, such as antiferromagnetic domain walls (DWs), have attracted much interest lately due to their robustness against external magnetic noise, their generic detection via conventional magnetometry remains a challenging task. Here, we propose quantum relaxometry as a new route to image spin textures by probing the collective spin modes harbored by them. We investigate the Goldstone modes hosted by an antiferromagnetic domain wall and assess the relaxation rate of a quantum-spin sensor interacting with them. We show that such modes can be detected via relaxometry in some common antiferromagnets. Moreover, based on symmetry considerations, we propose a strategy for probing the individual dynamics of each mode.

Introduction. Over the last few decades, ferromagnets have engendered the dominant material platform for exploring spin-based phenomena and devices [1]. Recently, antiferromagnets have emerged as the next-generation systems with a potential for constructing denser and faster spintronic devices [2]. Antiferromagnets derive their advantage from the fact that the Néel order parameter encoding the information is composed of a set of strongly-coupled oppositely-oriented spins. This results in a vanishing net magnetic moment, which makes the information robust against external magnetic noise. Consequently, computer elements composed of antiferromagnets can be packed closer than their ferromagnetic counterparts without undesired dipolar interaction-induced cross talks, giving a route to higher density. Secondly, the inherent spin dynamics are governed by the exchange coupling between the oppositely oriented spins and lies in the THz regime (as opposed to GHz frequencies in ferromagnets), paving the way for faster computation. In order to achieve this goal, phenomena allowing for imaging of the Néel order down to nanoscale in a non-invasive manner and operating in ambient conditions will play a crucial role. However, the absence of net magnetic moment presents a significant challenge in adapting the widely-used nanoscale imaging techniques for ferromagnets to antiferromagnets [3]. In particular, imaging techniques to characterize domain walls in a generic antiferromagnet are needed, as they will provide the basis for building antiferromagnet-based single-domain and domain-wall-based devices [4].

On another front, atomic-size quantum spin systems have recently surfaced as precision sensors of nanoscale magnetic fields in a variety of solid-state systems [5]. Among these, quantum-impurity (QI) spins hosted by the Nitrogen-vacancy (NV) defects in diamond are particularly interesting owing to their ability to operate at room temperature [5, 6]. Notably, NVs have been recently deployed to image domains and spin cycloids in antiferromagnets Cr2O3 [7] and BiFeO3 [3], respectively. However, in these demonstrations, NVs sense the Néel order via imaging the static magnetic fields emanating from a non-zero magnetic moment, which is imprinted by the textured Néel order [8]. These demonstrations are thus limited to the special class of magnetoelectric antiferromagnets. In contrast to the modality of imaging static magnetic fields, a scheme to sense the magnetic noise generated by collective spin modes has been recently established [9]. Within this method, referred to as relaxometry, fluctuating magnetic fields resonant with the NVs’ spin transitions are detected by monitoring the change in relaxation rate caused by the magnetic noise. In this

FIG. 1. (a) Detection scheme proposed in the text. The color gradient represents the $z$ component of the Néel order parameter, $l_z$. The antiferromagnet hosts a DW along the $x$ axis (dashed red line). Within the DW width $\lambda$, the order parameter (black arrow) lies within the $xy$ plane. Its dynamics engender the spin density $m$. The associated stray field is detected by the QI spin. (b) Collective field variables representing the soft modes of the DW. (c) Dispersion relations of the string and spin superfluid modes harbored by the DW. For the former, the dispersion relation deviates from $\omega = ck$ at $k \approx \lambda^{-1}$ due to the bending stiffness. The dashed line corresponds to the bulk spin waves (SWs) away from the DW.
Letter, invoking relaxometry, we present a new scheme for overcoming the challenge of imaging domain walls in a generic antiferromagnet. The proposed imaging method, schematically depicted in Fig. 1(a), amounts to measuring the relaxation rate of a quantum-spin sensor while its position scans the antiferromagnetic film. Within the proposed scheme, we take advantage of the difference in the strength of the magnetic noise generated by the bulk and domain wall regions. Specifically, within a broad frequency range, we predict a significant increase of the relaxation rate when the sensor approaches the DW region. This enhancement stems from the interactions between the quantum spin and the Goldstone modes rooted in the DW dynamics.

Detection scheme. We consider a quantum-impurity spin $\mathbf{S}$ oriented along the anisotropy axis $\mathbf{n} = (\cos \theta_s \sin \phi_s, \sin \theta_s, \cos \theta_s)$, as shown in Fig. 1(a). With an NV center in mind [10], we set $|S| = 1$. The local spin density $\mathbf{m} (\tilde{r})$ of the magnetic film gives rise to a stray field $\mathbf{B}(\tilde{r}_s) = \gamma \int d^3r \mathcal{D}(\tilde{r}, \tilde{r}_s) \mathbf{m}(\tilde{r})$ at the QI position $\tilde{r}_s = (0, 0, d)$, with $\gamma$ being the gyromagnetic ratio of the magnetic film and $\mathcal{D}$ the tensorial magnetostatic Green’s function [11, 12]. Before focusing on a specific model of the antiferromagnet, we highlight, invoking symmetry arguments, the differences in the magnetic noise sensed by the QI spin when it is placed over the bulk and the domain wall region.

When the quantum spin interacts with the spin density of a bulk region of a $U(1)$ symmetric and translationally invariant film, the QI relaxation rate at the frequency $\omega$ is given, to leading order in perturbation theory, by [13]

$$\Gamma(\omega) = f(\theta_s) \int dk k^3 e^{-2kd} [C_{xx}(k, \omega) + C_{zz}(k, \omega)],$$

(1)

where $f(\theta_s) = (\gamma \tilde{\gamma})^2 (5 - \cos 2\theta_s)/16\pi$ and $\tilde{\gamma}$ is the QI gyromagnetic ratio. Here, $C_{\mu\nu}(k, \omega)$, for $\mu, \nu = x, y, z$, is the spin-spin correlation function, which, at thermal equilibrium, can be related to the imaginary part of the spin susceptibility, $\chi''_{\mu\nu}(k, \omega)$, as $C_{\mu\nu}(k, \omega) = \coth (\beta \hbar \omega/2) \chi''_{\mu\nu}(k, \omega)$, where $\beta = 1/k_BT$, with $k_B$ being the Boltzmann constant and $T$ the temperature. [14]

The QI relaxation rate stemming from the first term on the right-hand side of Eq. (1), i.e., $C_{xx}$, can be attributed to one-magnon processes [13]. For spin waves with energy gap $\Delta$ and relaxation time $\tau_s$, the one-magnon contribution to the QI relaxation rate decays within the subgap region, vanishing at frequency $\omega \lesssim \Delta - 1/\tau_s$, while generally dominating the overall relaxation rate at higher frequencies [13]. The longitudinal noise $C_{zz}$, on the other hand, depends on the transport of the (approximately) conserved component, $m_z$, of the spin density, reflecting the collective two-magnon response [13].

Let us now consider the quantum spin to be placed above a domain wall of width $\lambda$, as illustrated in Fig. 1(a). As we discuss in detail later on, the DW dynamics can be described in terms of two independent Goldstone modes. The translational-symmetry restoring mode corresponds to fluctuations of the DW position. The mode emerging from the spontaneous $U(1)$-symmetry breaking coincides, instead, with planar rotations of the Néel order parameter, and its dynamics parallel the ones of a spin superfluid [15]. We take the distance $d$ between the quantum spin and the magnetic film to be much larger than the DW width, i.e., $d \gg \lambda$. This assumption allows us to relate the spin susceptibility of the magnetic film to the one associated with the one-dimensional DW modes as $\chi(\tilde{r}_s, \tilde{r}_s'; \omega) = \chi(\tilde{r}_s, \tilde{r}_s; \omega) \delta(y_t) \delta(y_j)$, with $\mu, \nu = x, y, z$.

The spin-superfluid dynamics give rise to a finite out-of-plane spin density (per unit of length), while the corresponding planar spin density is fomented by rigid DW translations. Thus, the longitudinal and transverse spin fluctuations do not interfere and can be considered separately, i.e., $C_{xx} = C_{yy} = 0$. We focus on a Néel and a Bloch DWs, whose planar spin density (per unit of length) lies along the $x$ and $y$ direction, respectively. Hence, for a Néel (Bloch) DW there is only a transverse one-magnon contribution to the QI relaxation rate de-
Model and results. Next, we evaluate the noise from hydrodynamic fluctuations in a bipartite antiferromagnetic film with uniaxial anisotropy along $z$. At temperatures much lower than the Néel temperature $T_N$, the long wavelength dynamics can be described in terms of coarse-grained continuous fields $I(\vec{r})$ and $m(\vec{r})$, corresponding, respectively, to the Néel order parameter along the staggered magnetization (with $|I(\vec{r})| = 1$) and the nonequilibrium spin density already introduced. The Lagrangian reads as

$$\mathcal{L}[l, m] = \int d\vec{r} \{m \cdot (1 \times \partial_t l) - H[l, m]\},$$

where $H[l, m] = \frac{1}{2} \int d\vec{r} \left[ A \left(\nabla l\right)^2 + K [z \times l]^2 + \frac{m^2}{\chi} \right]$. (4a)

Varying Eq. (4a) with respect to $m$ leads to the constitutive relation $m = \chi \times \partial_t l$ [16, 17]. Equation (4b) expresses the free-energy cost of deviations from collinear order along $z$, where $A$ is the order-parameter stiffness, $K$ the easy-axis anisotropy, and $\chi$ is the uniform static transverse (to the Néel order parameter) spin susceptibility. Dissipation can be introduced by means of the Rayleigh function $\mathcal{R}[l] = \alpha s \int d\vec{r} (\partial_t l)^2/2$, where $\alpha$ is the (dimensionless) Gilbert damping constant and $s$ the saturated spin density of both sublattices. From this model, we find for the imaginary part of the bulk transverse spin susceptibility [18]:

$$\chi''_{zz}(k, \omega) = 2\chi \omega^2 \frac{2\omega/\tau_s}{(\omega_k^2 - \omega^2)^2 + (2\omega/\tau_s)^2},$$

where $\omega_k = \sqrt{c^2 k^2 + A^2}$ (with $k = |\vec{k}|$) is the bulk SW dispersion and $\tau_s = 2\chi/\alpha c$. Here, $c = \sqrt{A/\chi}$ is the SW velocity, $\Delta = \Delta_0/\chi$ the anisotropy gap. Treating the transport of the $z$ component of the spin density as diffusive, we find for the imaginary part of the bulk longitudinal susceptibility [13]:

$$\chi''_{zz}(k, \omega) = \chi || \frac{\omega Dk^2}{(Dk^2 + 1/\tau_s)^2 + \omega^2},$$

where $\chi ||$ is the uniform static longitudinal susceptibility and $D$ the SW diffusion coefficient.

The model (4) admits also a solution for a static domain wall of width $\lambda = \sqrt{A/\Delta}$ and finite energy density (per unit length) $\sigma = 2\sqrt{\alpha K}$. Supposing the typical situation of the anisotropy $K$ being much weaker than the antiferromagnetic exchange interaction $A$, the domain wall width $\lambda$ is much larger than the atomic spacing, which justifies our long wavelength treatment based on the σ model, i.e., Eqs. (4a) and (4b). For boundary conditions of the form $l_{x}(y \rightarrow \pm \infty) = \pm 1$ and using the parametrization $l = (\cos \phi \sin \theta, \sin \phi \sin \theta, \cos \theta)$, the DW solution is given by

$$\cos \theta (\vec{r}) = \tanh \frac{y - Y}{\lambda}, \quad \phi (\vec{r}) = \Phi.$$ (7)

Here, $Y$ and $\Phi$ correspond, respectively, to the center position of the domain wall and the azimuthal angle therein [19]. As a result of the translational and $U(1)$ symmetries of the Hamiltonian, the energy density $\sigma$ does not depend on these parameters. The corresponding Goldstone modes can be described by promoting $Y$ and $\Phi$ to dynamic field variables with values along the DW length, as represented in Fig. 1(b).

Unlike for ferromagnets [20], here small perturbations of $\Phi(x)$ and $Y(x)$ are dynamically independent. We can introduce the following auxiliary variables:

$$M_z (x) = \int dy \, z \cdot m (\vec{r}), \quad \Pi (x) \equiv \frac{1}{\lambda} \int dy \, \left[ l (\vec{r}) \times m (\vec{r}) \right].$$

The $z$-projected spin density (per unit length) $M_z (x)$ corresponds to the generator of rotations around $z$, of the form $\{l (\vec{r}), \Pi (x')\} = \delta (x - x')$, with $\{\ldots\}$ being the Poisson brackets in the corresponding Hamiltonian description. This canonical pair describes the dynamics of the $z$ component of the spin density within the DW ascribed to planar rotations of the Néel order parameter. The imaginary part of the spin susceptibility associated with this mode reads as

$$\chi''_{zz}(k, \omega) = 2\lambda \chi_1 \omega^2 \frac{2\omega/\tau_s}{(\omega_k^2 - \omega^2)^2 + (2\omega/\tau_s)^2},$$

with $\omega_k, s = \alpha c$ being the dispersion relation of the superfluid mode [21] within the antiferromagnetic gap, depicted in Fig. 1(c). The field $\Pi (x)$, on the other hand, generates translations of the domain wall, $\{Y (x), \Pi (x')\} = \delta (x - x')$. These can be interpreted as the position and linear-momentum density of a clamped string with mass density $g = \chi \lambda$ subjected to a lateral tension $\sigma$. For a Néel DW, the associated spin response at long wavelengths can be written as

$$\chi''_{yy}(k, \omega) = \frac{\pi^2 \chi_1 \omega^2}{2} \frac{2\omega/\tau_s}{(\omega_k^2 - \omega^2)^2 + (2\omega/\tau_s)^2}. $$

For a Bloch DW, one has $\chi''_{xx}(k, \omega) = \chi''_{yy}(k, \omega)$ in Eq. (10). As shown in Fig. 1(c), this branch eventually deviates from linear dispersion at wavelengths $\sim \lambda$ due to the bending rigidity of the string, $\kappa \approx \lambda A$.

For a quantitative estimate of the QI relaxation rate in correspondence of both a bulk region of the film and the domain wall, we consider a thin film of the cubic insulating RbMnF$_3$, a spin $S = 5/2$ antiferromagnet with $T_N \approx 83$ K and SW gap $\Delta \approx 1$ K. Writing $A = JS^2$ and $\chi = \hbar^2/8JS^2 a_0^2$ [22, 23], we take the Heisenberg exchange $J \approx 0.3$ meV and the lattice constant $a_0 \approx 4$ Å [24, 25]. As an upper bound for the two-magnon induced relaxation rate, we set $\chi|| = \chi$, which should be much larger than the value of the longitudinal susceptibility $\chi$ while in the Néel ordered phase. We can rewrite
the spin diffusion coefficient as $D = v t_mfp / 2$, where $v = c \sqrt{1 - (\beta \Delta)^2}$ is thermal SW velocity, and $t_mfp$ the magnon mean-free path. Finally, we take $\gamma(\gamma) \approx 2 \mu_B / h$, where $\mu_B$ is the Bohr magneton, $t_mfp \approx 100$ nm, $d \sim 20$ nm, $\delta \sim d / 5$, $\alpha \sim 10^{-3}$ and $T \sim T_N / 5$.

Figure 2(a) shows the relaxation rate due to one- and two-magnon processes in the absence of spatial inhomogeneities. In Fig. 2(b), we plot the relaxation rate due to the modes of a Bloch DW, for both $n \parallel z$ and $n \parallel y$ [26]. By comparing Fig. 2(a) and 2(b), one can see that, over a broad frequency range, the relaxation rate induced by the DW modes is some two order of magnitude higher than the one associated with the coherent and incoherent bulk SW dynamics. To understand this, we compare, for $n \parallel z$, the maximum value of the relaxation rate due to the background one-magnon noise, $\Gamma_1(\omega) = g(\omega) \int d k d e^{-2 k d} \chi''(k, \omega) / 8 \pi w$, with the one associated with the spin-superfluid mode, i.e., $\Gamma(\omega) = 16 g(\omega) \int d k d k' K_1(2 \pi d / k') \chi''(k, \omega) / \pi$, where $g(\omega) = \coth(\beta \omega / 2) / (\gamma(\gamma))$ and where $K_1(z)$ is a modified Bessel function of the second kind [27]. The relaxation rates are maximized at the respective resonance frequency and for $k / \delta \sim 1 / d$ [13]. When both conditions are met, we find that, for $\omega_1 / d \ll \beta^{-1}$, $\Gamma(\omega) / \Gamma_1(\omega) \approx 2^3 \delta / \lambda$, in agreement with our numerical results. The relaxation time induced by the Bloch DW dynamics, at $\omega \approx 10$ GHz for $n \parallel z$, can be estimated as $\Gamma^{-1} \sim 10$ ms, shorter than the intrinsic one of, e.g., an NV center, which can reach seconds at similar temperatures [28].

We can probe the individual noise of each DW modes by applying an external magnetic field and tuning the orientation of the QI impurity spin. A field oriented along $y$ can both open up a gap $\Delta_s$ in the spin superfluid dispersion and enforce a DW Bloch profile. For a QI frequency $\omega < \Delta_s - 1 / \tau_s$, the QI relaxation rate due to the spin superfluid mode becomes negligible. By orienting the QI spin along $y$, the QI relaxation rate associated with the string mode vanishes as well. Finally, we note that our discussion is valid as long as the magnetic-field strength is lower than the one triggering the spinflop transition [16].

**Discussion and conclusions.** In this work, we propose quantum-impurity relaxometry as a spectroscopic imaging method for spin textures. We show that this technique allows to detect both the position of a spin texture and the dynamics of the Goldstone modes harbored by it. While here we have focused specifically on probing an antiferromagnetic domain wall, our approach could be extended to other nontrivial spin textures such as, e.g., antiferromagnetic skyrmions. Furthermore, our approach is general and it can be easily extended to more complex antiferromagnetic structures than a two-sublattice antiferromagnetic system. Our results indicates that, by, e.g., embedding a QI spin on a tip and scanning the sample [29], the position of a domain wall can be detected in correspondence of a significant increase of the QI relaxation rate within a broad frequency range.

Future work should address the detection of spin-superfluid transport properties when the spin-superfluid mode is populated coherently by, e.g., attaching metallic reservoirs at the two terminations of the DW [20], or in the context of two-fluid dynamics [30]. Furthermore, it has been recently predicted that the spin-superfluid current decays through phase slips, triggering the emission/absorption of skyrmions of the Néel order [20], whose proliferation can be controlled by the external bias. Probing these non equilibrium dynamics via quantum-impurity relaxometry is another interesting direction for future work.

[16] In the presence of an external field $\mathbf{h}$, we have the substitution $\partial I \rightarrow \partial I - \gamma I \times \mathbf{h}$ in the kinetic term of the Lagrangian (4a), leading to $m = \chi I \times (\partial_t I - \gamma I \times h)$ upon variations of $m$ [17]. Here, $\gamma$ is the gyromagnetic ratio of the magnet. This Lagrangian is valid as long as $\gamma I |h| \ll s$.

[26] The relaxation rates associated with a Néel domain wall display similar dependence on the QI frequency and are of the same order of magnitude.

[27] While we have focused on the relaxation rate associated with the spin superfluid mode for $n \parallel z$, choosing the string mode and/or any other QI orientation (with the exception of $n \parallel y$ for a Bloch DW) would lead to a similar relaxation rate.
