Placenta-Derived Exosomes and Gestational Diabetes Mellitus

Xuemin Liu, Hui Qiu

Department of Obstetrics and Gynecology, Shengjing Hospital of China Medical University, Shenyang, Liaoning Province, 110004, People’s Republic of China

Abstract: Gestational diabetes mellitus (GDM) refers to different degrees of glucose metabolism abnormalities that occur or be first discovered during pregnancy. It is closely related to many adverse pregnancy outcomes. Placenta-specific exosomes are one kind of extracellular vesicles which are only produced by the placenta. These exosomes participate in many physiological and pathological processes of the body through the contained RNA, lipids, proteins, and DNA. In gestational diabetes, the placental exosomes play an important role in the occurrence and development of gestational diabetes through regulating insulin resistance, inflammatory factors, and endothelial cell dysfunction. In this review, we will discuss the generation, changes, and mechanism of placenta-specific exosomes in GDM, as well as their prospects as a predictive and therapeutic target for gestational diabetes.

Keywords: pregnancy, gestational diabetes, exosome, placenta

Introduction

Gestational Diabetes Mellitus (GDM) refers to different degrees of glucose metabolism abnormalities that occur or be first discovered during pregnancy.\textsuperscript{1} It is generally considered to be insulin resistance caused by pancreatic β-cell dysfunction.\textsuperscript{2} The frequency of gestational diabetes mellitus at collaborating centers was 17.8% according to the International Association of Diabetes in Pregnancy Study Group criteria.\textsuperscript{3} GDM not only increases the risk of gestational hypertension, premature delivery, premature rupture of membranes, fetal malformations, dystocia, cesarean section, etc., but also increases the risk of metabolic syndrome, type 2 diabetes, and cardiovascular disease in offspring.\textsuperscript{4–6} Early diagnosis, intervention, and treatment can improve the prognosis of gestational diabetes. At present, the pathogenesis of gestational diabetes is not fully understood. Possible mechanisms include genetics, insulin resistance, autoimmunity, and the release of inflammatory factors.\textsuperscript{7–9} Clarifying the pathogenesis of gestational diabetes is of great significance to its diagnosis and treatment. During pregnancy, the placenta participates in the regulation of the endocrine system by secreting a variety of substances including exosomes. The role of placenta-derived exosomes in the etiology and progression of complications of pregnancy is still in a formative stage. This article summarizes the research progress of placenta-derived exosomes and GDM for providing new ideas for the pathogenesis and prevention of GDM.

Placenta and GDM

The placenta is an important organ for the exchange of substances between the fetus and the mother. The placental barrier can also shield the fetus from harmful substances; In addition, the placenta synthesizes a variety of enzymes, hormones, and cytokines to maintain normal pregnancy.\textsuperscript{10} It is estimated that 69% of all human proteins are expressed in the placenta and most of them are associated with pregnancy, estrogen biosynthetic, and metabolic pathways.\textsuperscript{11} During pregnancy, the placenta secretes many insulin-resistant hormones such as placental prolactin, estrogen, progesterone, and adrenal cortex hormones.\textsuperscript{12} As pregnancy progresses, the secretion of placental hormones gradually increases, making pregnancy a physiological insulin resistance state. Glucose metabolism is characterized by increased glycogen production and decreased utilization of glucose by tissues, which smooths the transfer of nutrition to the fetus.\textsuperscript{13–16} When facing...
insulin resistance, normal pregnant women can secrete enough insulin to supply the body’s needs, while a small number of pregnant women with defective β cell function cannot secrete so much insulin, unable to overcome insulin resistance, leading to gestational diabetes. At the same time, maternal hyperglycemia affects the structure of the placenta and the distribution of blood vessels and increases maternal and fetal complications. Therefore, the placenta plays an important role in the occurrence and development of gestational diabetes.

Exosomes
Exosomes are one kind of extracellular vesicles (EVs). Extracellular vesicles are derived from membranes in almost all cells and participate in the regulation of human functions through the contained RNA, lipids, proteins, and DNA. Based on their source, morphology, and the way they are released into the extracellular environment, extracellular vesicles are divided into three types including apoptotic bodies, exosomes, and microvesicles (MV). Exosomes are 50–120 nm in diameter and can uniquely reflect the phenotype of their parent cell. They were first discovered in 1981 by Trams et al. In 1984, Harding and Stahl described the release of small vesicles and tubules from rat reticulocytes. Exosomes are present in almost all biological fluids such as blood, saliva, lymph, amniotic fluid, milk, lachrymal, and mammary gland secretions etc. Methods to isolate exosomes include differential centrifugation, density gradient centrifugation, size exclusion chromatography, filtration, polymer-based precipitation, immunological separation, and isolation by sieving. As an important intercellular signal transduction carrier, exosomes work by interacting with the recipient cells. After being taken up, exosomes release their contents into the new host cells and exert their biological functions. The endocytosis process is achieved through phagocytosis or receptor and raft-mediated endocytosis. Adhesion is another form of interaction between exosomes and target cells, which is facilitated by the transmembrane proteins on the surface of the exosomes. Through these methods, exosomes participate in the regulation of a variety of normal physiology and diseases.

Placenta-Derived Exosomes (PdE)
Many exosomes are only expressed in the human placenta, the so-called placenta-derived exosomes. These placenta-derived exosomes carry signals in the form of RNA, proteins, lipids, and DNA. During pregnancy, exosomes are released from the placenta into the maternal blood circulation and participate in placental development and maternal immune tolerance. CD63 is a widely accepted exosomal marker. Placenta-derived exosomes can be differentiated from other exosomes by the presence of placenta-specific proteins or miRNAs such as placental alkaline phosphatase (PLAP). The total amount and the specific placenta-derived exosomes could be determined by quantum dots coupled with CD63 and PLAP antibodies, respectively. The exosomes are identified in maternal plasma as early as 6 weeks of pregnancy. The number of exosomes and the concentration of placenta-derived exosomes in maternal circulation increased significantly with the progression of pregnancy, with maximum numbers at term. Some miRNA clusters are specific to trophoblasts. The placenta-specific miRNA clusters are C19MC and C14MC. Morales-Prieto et al. explored that 34 of 46 miRNAs belonging to C14MC were downregulated in the third-trimester trophoblasts, while 46 out of 47 miRNAs belonging to C19MC were upregulated. The known function of placental exosomes in normal pregnancy are as follows:

Maternal-Fetal Communication
High levels of miRNAs can be found in the maternal blood during pregnancy and rapid decline in the first 24h postpartum, which suggests that there is a miRNA-based maternal-fetal communication. One study showed that placental miRNA can traffic to the maternal circulation with compartment-specific expression and that maternal miRNA can traffic to the placenta and even into the fetal compartment. Exosomal trafficking and function were also demonstrated by injecting fetal cell-derived fluorescently labeled exosomes into pregnant mice and by using genetically engineered mice in which fetal and maternal exosomes could be distinguished. These studies suggest that miRNAs are involved in the communication between the placenta and the fetal-maternal compartment.
Transfer Gene Information to Target Cells

Exosomes include many kinds of molecules, of which miRNAs are the most concerned. It is estimated that more than half of human gene expression is regulated by miRNAs. C19MC-derived miRNAs are expressed in human placental trophoblasts and secreted into the maternal circulation via exosomes where they can target maternal tissues. Fetal exosomes can also reach maternal gestational tissues. Foetal lung-derived C4BPA plays a role in birth timing determination. C4BPA can bind to CD40 of placental villous trophoblast to promote p100 processing to p52 and then activate the NF-κB pathway in the placenta, which contribute to the timing of birth. Bioinformatic analysis suggests that MIR517A is possibly participating in tumor necrosis factor-mediated signaling. The exosomal miR-512-3p participates in human trophoblast functions by targeting PPP3R1, encoding a regulatory subunit of calcineurin. BeWo exosomal miR-517a-3p was internalized into Jurkat cells and subsequently suppressed the expression of PRKG1 in recipient Jurkat cells. Besides miRNAs, transfer RNAs (tRNA) have been identified in syncytiotrophoblast-derived extracellular vesicles which alter gene expression in target cells. Most tRNAs within syncytiotrophoblast extracellular vesicles were 5'-tRNA halves. This suggests a novel mechanism for maternal-fetal signaling in normal pregnancy.

Inhibition of Maternal Immune Tolerance

During pregnancy, the maternal immune system needs to be in a state of tolerance to maintain the survival and growth of trophoblasts. The placenta-derived exosomes are immunosuppressive and promote fetal allograft survival by influencing many mechanisms. Decidual macrophages play an important role in this process. Trophoblasts produce a variety of components to induce decidual macrophages to differentiate into M2 types. Trophoblast-derived exosomes increased monocyte migration and produced large amounts of cytokines such as interleukin (IL)-1β, IL-6, Serpin-E1, granulocyte colony-stimulating factor, granulocyte/monocyte colony-stimulating factor, and TNF-α. Fas-induced T cell apoptosis is the main mechanism of immune tolerance. Exosomes from term-delivering pregnancies are significantly higher and exhibit greater suppression of CD3-zeta and JAK3. These placenta-derived membrane fragment isolates are capable of inducing FasL-mediated apoptosis and down-regulating CD3-zeta expression, which may contribute to the immune tolerance of the fetus. Placental exosomes carrying Fas ligand (FasL) and TRAIL mediate the immune privilege of the fetus by transmitting apoptosis signals during pregnancy. The increase in th2 cell secretion and the decrease in th1 cytokine secretion can also protect the fetus from the maternal immune system. Exosomes derived from villous cytotrophoblasts (VCT) reduced the production of Th1 cytokines in PBMCs, which was mediated by exosome-associated syncytin-2. NK cell receptor NKG2D was expressed and secreted via placental exosomes, which down-modulated the cognate receptor expression and might be a possible fetal immune escape mechanism. These results indicate that trophoblast-derived exosomes play an important role in maternal adaptation to pregnancy and fetal immune tolerance.

Regulate Angiogenesis and Endothelial Cell Migration

Remodeling of uterine spiral arteries by extravillous trophoblast cells is fundamental for pregnancy. This process requires invasion and differentiation of trophoblast cell. Placenta-derived exosomes contain biologically active proteins that can interact with the maternal endothelium and regulate their function. These exosomes can also induce extravillous cytotrophoblast cell invasion and proliferation in a time- and dose-dependent manner. It has been reported that trophoblast-derived MMP-12 mediates elastolysis, induces disruption of uterine vascular smooth muscle cell architecture, and favors extravillous trophoblast invasion during uterine spiral artery remodeling. Exosomes derived from human term placental tissue mesenchymal stem cells stimulated both endothelial tube formation and migration and enhanced angiogenesis-related gene expression. These changes induced by exosomes are critical for the normal growth and development of the fetus.

Placental Barrier

Placenta is the primary barrier between the maternal and fetus, which can protect the fetus from virus infection in the mother’s body. The specific mechanism is not fully elucidated. The exosomes produced and released by placental
trophoblasts play an important role. The microRNAs contained in placental exosomes restrict viral infections in autocrine and paracrine manners without depending on type III IFN signaling. Autophagy is a conserved vacuole/lysosome-mediated degradation pathway for clearing and recycling cellular components, which is involved in limiting inflammation signals upon virus invasion. When the placenta is infected with a certain type of virus, placental trophoblasts release a large number of exosomes, which deliver their miRNAs to maternal, fetal, or placental cells to alter gene expression, eventually inducing autophagy, followed by virus degradation. At least three members of the C19MC family (miR517-3p, miR516b-5p, miR512-3p) exhibit these potent antiviral effects against RNA and DNA viruses through strongly inducing autophagy. Based on this antiviral feature, vitro-constructed miRNAs have been used as a vaccine or therapeutic target against SARS-CoV-2.

Changes and Mechanisms of pdE in GDM

It was reported that the plasma concentration of total and placenta-derived exosomes was higher in GDM compared with the normal pregnancy matched by gestational age even during early pregnancy. However, the ratio of placental exosomes to total exosomes was lower in GDM pregnancies. Hyperglycemia and hypoxia are risk factors for metabolic complications during pregnancy. In order to test the effect of extracellular glucose concentration on exosomal signaling, first-trimester primary trophoblast cells were incubated under different concentrations of glucose and oxygen. The results showed that glucose (25 mM) significantly increased the release of exosomes from trophoblast cells at all oxygen tensions tested. The released exosomes significantly increased the release of all cytokines from human umbilical vein endothelial cells except IL-2 and IL-10. High glucose increased the release of exosomes from HUVECs, and the increased exosomes mimicked some of the effects of high glucose. Hypoxia (i.e., 1% O2) promotes the release and activity of cytotrophoblast-exosomes, thereby promoting extravillous trophoblasts invasion and proliferation. Hypoxia also increases the release of exosomes from placental mesenchymal stem cells, placental microvascular endothelial cells migration, and tube formation. These changes may contribute to placental vascular adaptation to low oxygen tension under both physiological and pathological conditions. The number of exosomes in the maternal blood circulation is closely related to BMI. 12–25% of exosomes in the maternal circulation come from the placenta. The contribution of placental exosomes to the total exosomal population decreases with higher maternal BMI across gestation. This study established that maternal BMI is an important factor affecting exosomal changes. Obesity increases the expression of some exosomal miRNAs in mice, including miR-192, miR-122, miR-27a-3p, and miR-27b-3p. Exosomes isolated from obese mice induce glucose intolerance and insulin resistance in lean mice. Adipose tissue exosomes in GDM increased the expression of glucose metabolism-related genes in placental cells. The up-regulated genes are associated with glycolysis, gluconeogenesis, glycogen production, and degradation. These suggested adipose tissue mediated the changes in placental function in GDM by inducing placental exosomes. The studies of placental exosomes in GDM are shown in Table 1.

Functions and Mechanisms of pdE in GDM

Exosomes contain numerous RNAs and transfer them between cells or organs, thereby establishing intercellular or interorgan communication. It has been identified that many mRNAs, lncRNA, and circRNAs are differentially expressed in umbilical cord blood exosomes of GDM patients. Bioinformatic analysis showed that the exosomal proteins in GDM are mainly associated with energy production, inflammation, and metabolism. The protein-protein interaction network revealed that the differentially expressed mRNAs were associated with the glucagon signaling pathway. Gene Ontology (GO) and Kyoto Encyclopedia of Genes and Genomes (KEGG) biological pathway analyses demonstrated that exosomal circRNAs and lncRNAs parental genes are involved in the regulation of the metabolic process, growth, and development were significantly enriched in umbilical cord blood of GDM. Most of the exosomal circRNAs and lncRNAs harbored GDM-related microRNA binding sites. These results showed that exosomal mRNAs, lncRNAs, and circRNAs are aberrantly expressed in the umbilical cord blood of GDM patients and play potential roles in GDM development and fetus growth.
Placental Exosomes and Insulin Resistance

Ten miRNAs (miR‒122-5p; miR‒132-3p; miR‒132-3p; miR‒136-5p; miR‒182-3p; miR‒210-3p; miR‒29a-3p; miR‒29b-3p; miR‒342-3p, and miR-520h) showed significantly higher levels in placenta of GDM cases. Bioinformatics analysis showed that these miRNAs are involved in insulin secretion/regulation and glucose transport in pregnant women. Exosomes isolated from placental explants from normal and GDM pregnancies show different miRNA profiles. Placental exosomes from GDM pregnancies decreased insulin-stimulated migration and glucose uptake in primary skeletal muscle cells obtained from normal pregnancies. However, placental exosomes from NGT increase migration and glucose uptake in skeletal muscle of diabetic subjects. Placental exosomes might have a role in the changes in insulin sensitivity in normal and GDM pregnancies. Mice infused with GDM small extracellular vesicles (sEVs) have attenuated glucose-stimulated insulin secretion, muscle basal insulin signaling, and insulin responsiveness, and are more likely to develop glucose intolerance. This result suggests sEVs can regulate maternal glucose homeostasis in pregnancy and contribute to the development of GDM. Tu et al reported that miR-409-5p was highly expressed in the serum of GDM patients and it is positively correlated with insulin resistance index (HOMA-IR). Qi et al found that the expression of miR-185 was downregulated in serum and placenta of GDM patients and is negatively correlated with HOMA-IR. miR-140-3p overexpression also contributes to the defective placental IR signaling in patients with GDM. Dipeptidyl peptidase IV (DPPIV) can regulate glucose-dependent insulin secretion by breaking down GLP-1. DPPIV-bound syncytiotrophoblast-derived extracellular vesicles were significantly increased in the circulation of GDM pregnancies. The cytokine tumor necrosis factor-alpha (TNF-alpha) has been implicated in the pathogenesis of insulin resistance in Type 2 diabetes mellitus via regulating glucose, lipid metabolism, and insulin resistance. Placental tissues from patients with GDM release greater amounts of TNF-alpha under conditions of high glucose, which may be related to the placental miRNA. The expression of miR-143, mitochondrial complexes were significantly decreased in A2GDM (controlled by medication) placentae, while human placental lactogen levels, expression of glycolytic enzymes, GLUT1, and mTOR signaling were significantly increased compared with A1GDM (controlled by diet). Overexpression of miR-494 improved insulin secretion and total insulin content, while in GDM, the miR-494 level was significantly decreased. These results suggest that placental exosomes promote the occurrence and development of GDM by regulating insulin resistance.

Placental Exosomes and Inflammation

Placental exosomes may contribute to maternal systemic inflammation during pregnancy. The exosomes of obese women increased the release of IL-6, IL-8, and TNF-α from endothelial cells. Exosomes isolated from GDM pregnancies can also significantly increase the release of proinflammatory cytokines from endothelial cells. Utilizing the BeWo cell line and whole placental explants, Holder et al demonstrated that macrophage exosomes were actively transported into the human placenta and induced the placenta to release proinflammatory cytokines. Exosome-encapsulated miR-6869-5p is significantly downregulated in placenta-derived macrophages of GDM patients, which may contribute to maintaining placental microenvironment balance by preventing inflammation. MiR-657 can promote the generation of inflammatory cytokines (IL-6 and TNF-α) and activation of NF-κB. The expression of miR-657 was increased in patients with GDM, which contributes to the pathogenesis of GDM via the IL-37/NF-kB signaling axis. The expression levels of miR-875-5p are downregulated in patients with GDM. Fu et al found that miR-875-5p regulated IR and inflammation by targeting TXNRD1 in GDM rats. Trophoblast-derived exosomes have been demonstrated to induce macrophages to synthesize and release pro-inflammatory factors through fibronectin. Upregulation of miR-518d may contribute to the pathology of the development of GDM, via an effect on the regulation of proliferator-activated receptor-α (PPARα) expression. We also found that miR-518d negatively regulates the expression of PPARα and triggers the nuclear transport process of NF-kB and phosphorylation of pathway-associated proteins leading to an inflammatory response and the development of GDM.

Placental Exosomes and Endothelial Cell Dysfunction

Placental exosomes can also regulate placental and fetal membrane endothelial dysfunction in gestational diabetes mellitus. High glucose increased endothelial wound healing and the expression of P–Ser1177-eNOS, hCAT-1,
Table 1 The Studies of Placental Exosomes in Gestational Diabetes Mellitus

| Reference | Target | Tissue | Results |
|-----------|--------|--------|---------|
| [92]      | PLAP+ EVs | Plasma | Presence of high levels of placental exosomes in GDM compared to normal through gestation |
| [106]     | PLAP+ EVs | Placenta | Placental exosomes were associated with skeletal muscle insulin sensitivity |
| [107]     | PLAP+ EVs | Placenta | FDE regulates glucose homeostasis |
| [111]     | PLAP+ EVs | Placenta | STB-EVs from GDM perfused placentae show greater DPPIV activity |
| [125]     | PLAP+ EVs | Placenta | ExGDM increased L-arginine transport, hCAT-1 and eNOS expression and activity, and p44/42mapk activation |
| [140]     | PLAP+ EVs | Plasma | Placental-derived exosomes increased ~2.1-fold in GDM compared to normal through gestation |
| [116]     | miR-494 | Placenta | MiR-494 downregulated |
| [118]     | miR-6869-5p | Placenta | MiR-6869-5p promoted M2 macrophage polarization and thus restrain inflammation |
| [122]     | miR-518d | Placenta | MiR-518d was higher in the placenta of GDM and was negatively correlated with the levels of PPARα protein |
| [123]     | miR-518d | Placenta | MiR-518d negatively regulates the expression of PPARα and triggers the nuclear transport process of NF-κB |
| [152]     | miR-516-5p, miR-517-3p, miR-518-5p, miR-222-3p, miR-16-5p | Urinary | All the miRNAs examined were downregulated in patients with GDM |
| [33]      | miR-508-3p, miR-27a, miR-9, miR-137, miR-92a, miR-33a, miR-30d, miR-362-5p, miR-502-5p | Placenta | 29 differently expressed miRNA in the array, 9 replicated by qPCR, miR-508-3p upregulated and the rest, down-regulated |
| [150]     | miR-223, miR-23a | Serum | AUC 0.91, sensitivity of 90%, specificity of 94% |
| [115]     | mir-143 | Placenta | 50% reduction in A2GDM (controlled by medication) but not A1GDM (controlled by diet) |
| [110]     | miR-140 | Placenta | MiR-140-3p overexpression contributes to the defective placental IR signaling in patients with GDM |
| [148]     | miR-132, miR-29a, miR-222 | Serum | The expression levels of three miRNAs were significantly decreased in GDM women |
| [147]     | miR-126-3p, miR-155-5p, miR-21-3p, miR-146b-5p, miR-210-3p, miR-222-3p, miR-223-3p, miR-517-5p, miR-518a-3p, miR-29a-3p | Plasma | Circulating early-mid-pregnancy miRNAs are associated with GDM, particularly among women who are overweight/obese pre-pregnancy or pregnant with male offspring |
| [143]     | miR-16-5p, miR-17-5p, miR-20a-5p | Plasma | AUC 0.92, 0.88, and 0.74 sensitivity 41.6%, 21.4% and 17.8% specificity 95.8%, 95.4% and 95.4% |
| [127]     | miR-101 | Umbilical cord vein | GDM impairs HUVEC function via miR-101 upregulation |

| [149]     | miR-16-5p, miR-29a-3p, miR-134-5p | Serum | AUC 0.687, sensitivity of 72.5%, specificity of 57.5% |
| [114]     | miR-657 | Placenta | Dysregulation of miR-657 contributes to the pathogenesis of GDM via IL-37/NF-κB signaling axis |
| [108]     | miR-409-5p | Serum | MiR-409-5p is highly expressed in the serum of patients with GDM, and it is positively correlated with the insulin resistance index |
| [109]     | miR-185 | Serum placenta | The down-regulation of miR-185 expression in serum and placenta of pregnant women with GDM is negatively correlated with HOMA-IR |

(Continued)
VEGF, and ICAM-1 by increasing the release of exosomes from HUVECs. Exosomes were isolated from HUVECs incubated with basal glucose reverted the effect of high glucose on endothelial cells. Rocío Salsoso found that ExN (Normal pregnancy -exosomes) and ExGDM (GDM-exosomes) cargo have differential effects in HUVECs. ExN restores GDM-reduced wound recovery but ExGDM delays wound recovery in normal pregnancies. ExN restores GDM-upregulated L-arginine/NO/p44/42mapk signaling but ExGDM increase it and ROS in normal pregnancies. Foetoplacental endothelium-derived exosomes maintain a GDM phenotype in HUVECs. The cell adhesion molecules (CAMs) promote attachment and trans-endothelial migration of leukocytes. Díaz-Pérez et al identified a reduction of ICAM-1 protein in fetoplacental endothelial cells in GDM pregnancy, which may be a kind of protection to avoid leukocyte transmigration into the placenta. MiR-101 is up-regulated by hyperglycemia and contributes to some of the defects of the umbilical cord vein (HUVECs) through the target gene EZH2 in GDM. These studies show that placental exosomes are associated with fetoplacental endothelial dysfunction in gestational diabetes mellitus.

**Placental Exosomes and Fetus Growth**

15–45% of newborns of women with gestational diabetes mellitus (GDM) are macrosomia. We know that the main cause of macrosomia in GDM is hyperglycemia and the increased insulin resistance of the mother, but the molecular mechanism is not very clear. MicroRNAs have been identified to regulate placental development and fetal growth. There was a significant positive correlation between the ratio of placental-derived to total exosomes and birth weight percentile. The contribution of placental exosomes to the total exosome concentration was significantly decreased in FGR cases compared to controls. 143 miRNAs were differentially expressed in the plasma samples from pregnant women with fetal macrosomia compared with the controls. Li et al demonstrated that miR-508-3p was up-regulated and may contribute to macrosomia through enhancing the EGFR-Pi3K-Akt signaling pathway. Jiang et al showed that the expression level of placental miR-21 was significantly upregulated in serum samples of macrosomia. High levels of miR21 expression and low levels of miR143 expression could predict the risk for macrosomia. The interaction of two miRNAs affects the risk of macrosomia through the mitogen-activated protein kinases signaling pathway. The low expression of miR-16 and miR-21 in the placenta is associated with small gestational age (SGA) status. MiR-17-92 clusters contribute to macrosomia development by regulating the cell cycle pathway and can also be used as a predictive biomarker for macrosomia. Some lncRNAs were aberrantly expressed in the umbilical cord blood from GDM macrosomia, which suggested lncRNAs might also play a role in fetal development. The functions and mechanisms of placenta-derived exosomes in GDM are shown in Figure 1.

| Reference | Target | Tissue | Results |
|-----------|--------|--------|---------|
| [105]     | miRNA profiles | Serum | Ten miRNAs showed significantly higher levels |
| [145]     | miRNA profiles | Serum | Total of 32 miRNAs, 12 were significantly upregulated and 20 were significantly downregulated in GDM |
| [103]     | miRNAs lncRNAs | Umbilical cord blood | 84 miRNAs and 256 lncRNAs as differentially expressed |
| [139]     | lncRNA profiles | Umbilical cord vein | Total of 8814 lncRNAs, 349 were significantly upregulated and 892 were significantly downregulated in GDM |
| [104]     | Circular RNA profiling | Placenta | Total of 48,270 circRNAs, 227 were upregulated and 255 down-regulated |
| [102]     | Circular RNA profiling | Umbilical cord blood | Total of 88,371 circRNAs. 229 circRNAs were up-regulated and 278 circRNAs were down-regulated |
| [151]     | Cell-free DNA | Serum | CfpDNA multiples of the median (MoMs) were lower in women who later developed GDM |

**Table 1 (Continued).**
PdE as Predictive Markers and Therapeutic Targets for GDM

Placental exosomes were significantly higher in pregnancies complicated by GDM than in normal pregnancies. Gestational age and pregnancy outcomes were the main factors of exosome concentration. Maternal body mass index, glucose concentration, and fetal body weight were also correlated with the concentration of placental exosomes, suggesting that exosomes may be involved in maternal metabolic adaptation to pregnancy. Rahimi et al detected dysregulation of Drosha, Dicer, and DGCR8 in GDM patients which are major enzymes in the miRNA biogenesis process. Therefore, they favor the hypothesis that miRNAs are involved in the development of GDM. Cao et al found that the expression of plasma microRNA-16-5p, −17-5p, −20a-5p from GDM women were significantly upregulated compared with non-GDM women. From these studies, it can be concluded that miRs are involved in the pathogenesis of GDM and have potential as diagnostic biomarkers for disease development.

It is reported that circulating early–mid-pregnancy (range 7–23 weeks of gestation) miR-155-5p and −21-3p levels were positively associated with GDM. The expression levels of three miRNAs (miR-132, miR-29a, and miR-222) were significantly decreased in GDM women compared with the controls at 16–19 gestational weeks. Serum miRNAs could be candidate biomarkers for predicting GDM. First-trimester cf DNA (cDNA from placental exosome) levels are associated with GDM. Placental exosomes isolated from the urine of GDM women show a differential profile expression of microRNAs across gestation, suggesting that urine is a potential biological fluid for the research of pathological conditions during pregnancy.

Given the role of miRNA in the mechanism of the occurrence and development of GDM, it is expected to use as a target to develop treatments for GDM. mir-21 can reverse high glucose and high insulin-induced IR in 3T3-L1 adipocytes, which may be a new therapeutic target for metabolic diseases. There are many ways to regulate miRNA levels in vivo, of which anti-miRs are the most widely used approaches. MiRNAs are small and comprise a known sequence, which makes anti-miRs have the potential to become a new class of drugs. At present, the research on this aspect is mostly in animal experiments, and the application of anti-miRs in gestational diabetes needs further study.
Conclusion
In gestational diabetes, hypoxia, high glucose, and BMI affect the production of placental exosomes, which in turn regulate insulin resistance, inflammatory factors, and endothelial cell dysfunction. These factors work together to promote the occurrence and development of diabetes and fetal growth and development. The diagnosis of gestational diabetes is very late, and there is still a lack of effective predictive methods. The content of placental exosomes can change in early pregnancy, and the detection of exosomes is expected to become an effective method for predicting GDM. Placental exosomes contain a variety of components. Except for mRNA, there are relatively few studies on other components of exosomes. The function and mechanism of most placental exosomes are still unclear. Clarifying the mechanism of exosomes in gestational diabetes is of great significance to its early prevention, diagnosis, and treatment.
