Abstract
Employing QCD sum rules the in-medium modifications of scalar charm mesons are estimated. The mass splitting of \( D^* - \bar{D}^* \) is quantified.

Keywords:
strongly interacting matter, in-medium modifications of hadrons, SU(3) sector of QCD, SU(2) sector of QCD, SU(2) sector of QCD

1. Introduction

In-medium modifications of hadrons, embedded in strongly interacting matter, are of considerable interest, since they test the non-perturbative sector of QCD. As density and temperature of the ambient medium can be changed in a controllable manner, the changes of hadron properties, compared to the vacuum, may serve as an in-depth check of our understanding of hadron physics.

Previous investigations focused on light vector mesons and light pseudoscalar strange mesons \([1, 2]\), thus being essentially restricted to the light-flavor SU(3) sector of QCD. The starting FAIR project will enable the extension to charm degrees of freedom. In fact, two major collaborations \([3, 4]\) plan to invest in-proton-nucleus and heavy-ion collisions. Given this fact, two major collaborations \([3, 4]\) plan to invest in-proton-nucleus and heavy-ion collisions. Given this fact, two major collaborations \([3, 4]\) plan to invest in-proton-nucleus and heavy-ion collisions. Given this fact, two major collaborations \([3, 4]\) plan to invest in-proton-nucleus and heavy-ion collisions.

2. QCD sum rules

The Borel transformed in-medium sum rules for the current-current correlator \( \Pi(q) = i \int d^4 x e^{iqx} \langle \langle \mathcal{T} [j(x)] j(0) \rangle \rangle \) (here, \( \mathcal{T} [\cdots] \) means the time-ordered product and \( \langle \cdots \rangle \) stands for Gibbs average) may be cast in the form (cf. \( \Box \) for details)

\[
\left( \int_{\omega_0}^{\infty} + \int_{-\infty}^{\omega_0} + \int_{-\infty}^{\infty} \right) d\omega \Delta \Pi(\omega, \bar{q}) e^{-\omega^2/M^2} = \pi Bq^\to M^2 \left[ \Pi_{\text{OPE}}(Q^2, \bar{q}) \right] \left( M^2 \right),
\]

where \( Q^2 = -q_0^2 \), \( \Delta \Pi \) are the discontinuities along the entire real axis, \( M \) is the Borel mass and the integral over the hadronic spectral function \( \Pi(s, \bar{q}) \) is split into a part of the low-energy excitations (first term) and the so-called continuum contributions (second and third terms). The latter ones are mapped by a semi-local duality hypothesis to expressions corresponding to the operator product expansion (OPE) of the correlator which yields \( B \left[ \Pi_{\text{OPE}}(Q^2, \bar{q} = 0) \right] \left( M^2 \right) \). Since particles and anti-particles behave differently in a nuclear medium at zero temperature, two sum rules emerge – an even one \( (j = j', j' = e) \) and an odd one \( (j = 0, j' = 0) \). The OPE’s needed here can be obtained by combining the OPE’s for pseudoscalar \( D \) mesons in \( \Box \) and the OPE’s for difference sum rules in \( \Box \):

\[
Bq^\to M^2 \left[ \Pi_{\text{OPE}}(Q^2, \bar{q} = 0) \right] \left( M^2 \right) = \frac{1}{\pi} \int_{m_0^2}^{\infty} ds e^{-s/M^2} \text{Im} \Pi_{\text{OPE}}(s, \bar{q} = 0) + e^{-m_0^2/M^2} \left( m_c \langle dd \rangle - \frac{1}{2} \left( \frac{m_c^2}{2M^2} - \frac{m_c}{M^2} \right) \langle d\bar{c}\tau Gd \rangle \right) + \frac{1}{12} \left( \frac{\alpha_s}{\pi} G^2 \right) + \left( \frac{7}{18} + \frac{1}{3} \ln \frac{m_0^2}{M^2} - \frac{2\gamma_E}{3} \right) \left( \frac{m_c^2}{M^2} - 1 \right) + \frac{2}{3} \left( \frac{m_c^2}{M^2} - 1 \right) \left( \frac{m_c}{M^2} - 1 \right) + 2 \left( \frac{m_c^2}{M^2} - 1 \right) \left( d^i \mathcal{D}_0 d \right) \]

Preprint submitted to Nucl. Phys. (Proc. Suppl.) November 12, 2010
\[ -4 \left( \frac{m^3}{2M^4} - \frac{m^2}{M^3} \right) \left[ (dD_{0}^d) - \frac{1}{8} (dG_{rG}d) \right], \]  

(2a)

\[ \mathcal{B}_{\mathcal{O} \to M^2} \left[ \Pi_{\mathcal{O} \to M^2}(\mathcal{O}^2, \hat{q} = 0) \right] (M^2) = e^{-m_0^2/M^2} \left( (d^2 D_{0}^d) - 4 \frac{m^2}{M^2} (d^2 D_{0}^d) \right) - \frac{1}{M^2} (d^2 G_{rG}d) \equiv e^{-m_0^2/M^2} (K(M)n), \]  

(2b)

where \( \text{Im} \Pi_{\mathcal{O} \to M^2} \) is given in [7] and \( m_0 = 1.3 \text{ GeV} \) is the charm quark mass. We define \( e \equiv \int_0^{\omega_0} d\omega \frac{\omega}{(\omega - \omega_c)} \) and \( o \equiv \int_0^{\omega_0} d\omega \frac{\omega}{(\omega - \omega_c)} \) to obtain, with a pole ansatz for the lowest excitations within \( \omega_c - \omega_c^* \), which couple with strengths \( F_{\pm} \) to the above currents,

\[
\begin{align*}
\epsilon &= m_s F_s e^{-m_s^2/M^2} + m_d F_d e^{-m_d^2/M^2}, \\
o &= F_s e^{-m_s^2/M^2} - F_d e^{-m_d^2/M^2}.
\end{align*}
\]

(3a)

(3b)

The mass splitting \( \Delta m \) and mass center \( m \) are related by \( m = m \pm \Delta m \). The following equations determine these quantities:

\[
\begin{align*}
\Delta m &= \frac{1}{2} \epsilon \omega_0 - \frac{\omega_0'^2}{\epsilon + \omega_0}, \\
m^2 &= \Delta m^2 - \frac{\epsilon \omega_0' + (\omega_0')^2}{\epsilon + \omega_0}.
\end{align*}
\]

(4a)

(4b)

where a prime denotes the derivative w.r.t. \( M^2 \) and \( \epsilon \) as well as \( \omega_0 \) are given by (2a) and (2b) minus the continuum parts from (1).

### 3. Low-density expansion

An expansion in the density \( n \) gives the leading term for the mass splitting

\[
\Delta m(n) \approx \frac{1}{2} \left. \frac{d\epsilon (0)}{d(n_0)} \right|_{n_0} - \left. \frac{d\epsilon (0)}{d(n_0)} \right|_{n_0 = 0} n \equiv \alpha_{\Delta m} n,
\]

(5)

since \( \epsilon(n = 0) \neq 0 \) and \( \omega_0(n = 0) = 0 \).

The primary goal of the present sum rule analysis is to find the dependence of \( \Delta m \) and \( m \) on changes of the condensates entering [2]. However, also the continuum thresholds \( \omega_0^2 \) can depend on the density. To study this influence, we consider the asymptotic splitting of the continuum thresholds \( \Delta \omega_0^2 = \frac{1}{2} (\omega_0^2 - (\omega_0^*)^2) \) and parameterize its density dependence by \( \Delta \omega_0^2(n) = \alpha_{\Delta m} n + \mathcal{O}(n^2) \), which leads to

\[
\left. \frac{d\epsilon}{dn_0} \right|_{n_0} = \frac{\epsilon - \omega_0^2/M^2}{\pi \alpha_{\omega_0}} \left. \text{Im} \Pi_{\mathcal{O} \to M^2}(\omega_0^2, d\Delta \omega_0^2/dn) \right|_{n_0 = 0} + e^{-m_0^2/M^2} (K(M)),
\]

(6a)

The perturbative terms stem from the continuum contribution in case of unequal thresholds for particle and antiparticle. In linear density approximation of the condensates the last terms become \( \epsilon/n \) and \( \omega_0'/n \), respectively. In this case, \( \alpha_{\Delta m} \) is given as

\[
\alpha_{\Delta m} = -\frac{1}{2 \epsilon(0)} \left( \frac{m_s^2(0) + \omega_0'}{n} + \epsilon - \omega_0^2/M^2 \right) \text{Im} \Pi_{\mathcal{O} \to M^2}(\omega_0^2) \left[ m^2(0) - \omega_0^2 \right] \alpha_{\Delta m},
\]

(7)

which is dominated by the non-perturbative terms. We choose the Borel mass range and the thresholds according to [3].

As an estimate for the order of \( \alpha_{\Delta m} \) we rely on the splitting of the thresholds for the pseudoscalar channel in [5] and obtain \( \alpha_{\Delta m} \approx 0.25 \cdot 10^3 \text{ GeV}^{-1} \). It is an overestimation of the pseudoscalar \( \mathcal{O}(n) \) threshold splitting as it would correspond to a linear interpolation of \( \Delta \omega_0^2 \) from the vacuum to nuclear saturation density and, hence, includes higher order terms in the density. We choose \( \alpha_{\Delta m} \approx 10^2 \ldots 10^3 \text{ GeV}^{-1} \).

The results are depicted in Fig. 1 for \( \alpha_{\Delta m} = \pm 10^2 \text{ GeV}^{-1} \) and for \( \alpha_{\Delta m} = \pm 10^3 \text{ GeV}^{-1} \) in Fig. 2. In Fig. 3 \( \alpha_{\Delta m} \) as a function of \( \alpha_{\Delta m} \) for \( M = 1.37 \text{ GeV} \), the minimum of the vacuum Borel curve for the scalar D meson, is displayed.

![Figure 1](image.png)
could raise the question if the splitting is mainly caused by a splitting of the thresholds and, hence, might be an artifact of the method which determines $\Delta\omega_0$. From the above study we find that $\alpha_{\Delta m}$ indeed influences the mass splitting. A direct correlation in the sense of a correlation in sign can not be confirmed. Furthermore, the results for $D_s$ mesons [5] allow for a positive mass splitting if the net strange quark density falls below a critical value. As the strange quark density enters through the vector quark condensate, this already points to a suppressed influence of the threshold splitting on the mass splitting.

4. Beyond low-density approximation

In [5], the threshold splitting is not considered as a free parameter but determined by the requirement that the minima of the Borel curves for particle and antiparticle are at the same Borel mass.

Following the same analysis strategy of [5] and employing the condensates listed in [5], one obtains the results exhibited in Figs. 4 and 5. This analysis goes beyond the strict linear density expansion of $m$ and $\Delta m$ and also takes into account quadratic terms in the density. The medium dependent part of the chiral condensate (the density dependence of which is only in linear density approximation, as the other condensates too) enters the mass splitting next to leading order of the density. The determination of the mass center $m$ depends strongly on the chosen center of continuum thresholds $m_0^2 = ((\omega_0^s)^2 + (\omega_0^a)^2)/2$ as indicated by the broad range in Fig. 5 when varying their medium dependence. In contrast, the splitting is fairly robust as evidenced by Fig. 1 where the difference between curves of different thresholds is negligible.

A linear interpolation of the threshold splitting from vacuum to a density of $n = 0.01 fm^{-3}$ gives an estimate for $\Delta m$.

References [5]
for the $O(n)$ term $a_{\Delta m} \approx 7 \cdot 10^2 \text{ GeV}^{-1}$, which justifies the range chosen in the previous section.

5. Conclusions

In summary we extend the recent analysis [5] of the QCD sum rules to lowest scalar $D^*$ mesons. The importance of the density dependence of the continuum thresholds is exposed. Going beyond the strict linear approximation in density one obtains a robust pattern of the splitting of scalar $D^* - \bar{D}^*$ mesons which resembles the one for pseudoscalars. A firm prediction of the absolute values of the respective scalar mesons is hampered by uncertainties in the determination of the mean mass. With the employed values of the condensates entering the truncated sum rule and within the employed analysis strategy a tendency of a "mass drop" may be deduced.

For the sake of simplicity we restricted our analysis to a pole + continuum ansatz. One can go beyond such simplified treatment of the hadronic spectral functions by considering moments. The latter ones do not longer allow for a simple interpretation but seem more appropriate for broad resonances. With respect to the research programme at FAIR, where precision measurements of various charm hadrons are envisaged, more model-independent studies are required.
