Collective cell migration requires vesicular trafficking for chemoattractant delivery at the trailing edge

Paul W. Kriebel, 1 Valerie A. Barr, 1 Erin C. Rericha, 1,3 Guofeng Zhang, 2 and Carole A. Parent 1

Introduction

A wide variety of cells have the ability to sense and migrate directionally along external gradients of chemoattractants. This process, called chemotaxis, is fundamental for a multitude of physiological processes including embryogenesis, angiogenesis, and wound healing. It is also important in the pathophysiology of asthma, arthritis, and metastatic invasion (Ridley et al., 2003). Upon exposure to a chemoattractant gradient, cells polarize, orient themselves, and migrate directionally. In this context, fast moving neutrophils and Dictyostelium discoideum cells are in a league of their own (Parent, 2004). These cells have the ability to sense extremely shallow chemoattractant gradients and quickly transduce them into highly polarized cellular responses, where F-actin is highly enriched at the front for pseudopod extension and myosin II is mainly assembled at the back for contraction and retraction. For both neutrophils and Dictyostelium, chemoattractants mediate their effects by binding to seven transmembrane G protein–coupled receptors. Activation of the receptors leads to dissociation of heterotrimeric G proteins into Go and Gα subunits and activation of multiple downstream effectors that ultimately give rise to cell polarity and migration (Van Haastert and Devreotes, 2004; Affolter and Weijer, 2005; Bagorda et al., 2006).

Dictyostelium has been invaluable to decipher the signal transduction mechanisms regulating chemotaxis (Kimmel and Parent, 2003; Franca-Koh et al., 2006). Upon starvation, these cells rely on chemotaxis to locate and migrate toward each other and form an aggregate that will differentiate into a multicellular organism. Remarkably, as the cells polarize and migrate directionally to form the aggregate, they do so by aligning in a head-to-tail fashion, forming characteristic chains of cells or streams. The ability of Dictyostelium cells to spontaneously aggregate and stream relies on the presence of an exquisitely regulated signal relay loop that is centered on cAMP. In this organism, the detection, synthesis, and degradation of cAMP are highly regulated (Kriebel and Parent, 2004). The addition of chemoattractants leads to a burst in the activity of adenylyl cyclase (ACA), requires vesicular trafficking. This trafficking results in a local accumulation of ACA-containing intracellular vesicles and involves intact actin, microtubule networks, and de novo protein synthesis. We also show that migrating cells leave behind ACA-containing vesicles, likely secreted as multivesicular bodies and presumably involved in the formation of head-to-tail arrays of migrating cells. We propose that similar compartmentalization and shedding mechanisms exist in mammalian cells during embryogenesis, wound healing, neuron growth, and metastasis.
which converts ATP into cAMP. Most of the cAMP produced is secreted and acts as a chemoattractant by binding to specific G protein-coupled receptors exposed at the cell surface (cARs; Parent and Devreotes, 1996b). Receptor stimulation leads to the activation of a variety of effectors, including ACA, which amplifies and relays the signal to neighboring cells. Finally, the extracellular concentration of cAMP is tightly controlled through the expression of membrane-bound and secreted forms of a phosphodiesterase and a specific phosphodiesterase inhibitor, allowing the signaling cascade to come back to basal levels and respond to further stimulation (Franke and Kessin, 1992).

We previously showed that transmission of chemotactic signals to neighboring cells is a spatially regulated process. When exposed to an external point source of cAMP, cells lacking ACA can migrate directionally but cannot relay the chemotactic signal to neighboring cells or align in a head-to-tail fashion to form streams. This streaming behavior not only depends on the presence of ACA but, most remarkably, on its enrichment at the back of polarized cells (Kriebel et al., 2003). We proposed that the asymmetrical distribution of ACA provides a compartment from which cAMP is locally released to attract neighboring cells to the back of cells ahead of them. We now report that vesicle trafficking on microtubules is required for the enrichment of ACA at the back of cells. Remarkably, we also establish that ACA-containing vesicles are shed at the back of migrating cells and that de novo ACA synthesis is essential to maintain the cellular distribution of ACA. Together, these findings showcase the mechanisms regulating the asymmetrical distribution of proteins in polarized cells and the controlled release of chemoattractants.

Results

Enrichment of ACA at the back of migrating cells depends on an intracellular pool of the enzyme

We used confocal microscopy to better define the partitioning of ACA in fully differentiated ACA-YFP/aca− cells. Fig. 1 A shows images of maximum intensity projections from a randomly migrating cell. There is a clear enrichment of ACA at the back of cells as well as the uniform staining at the cell periphery. In addition, ACA is seen on intracellular vesicles that move very rapidly across the cytoplasm (Video 1, available at http://www.jcb.org/cgi/content/full/jcb.200808105/DC1). Closer examination reveals that most vesicles are moving back and forth from a perinuclear aggregation center to the back of cells, whereas a smaller subset of solitary vesicles reach extending pseudopods. The same phenomenon is observed in cells subjected to a point source of chemoattractant (Fig. 1 B and Video 1). Upon closer examination, we observe that the ACA-enriched region at the back of cells corresponds to a dense accumulation of labeled vesicles, a phenomenon that is clearly substantiated by visualization of 3D reconstructions from confocal z stacks (Fig. 1 C and Video 2).

We next used FRAP to define the mechanisms responsible for establishing the asymmetrical distribution of ACA. In these experiments we photobleached part of the cell periphery and carefully monitored the fluorescence recovery over time. We reasoned that if the recovery is solely dependent on membrane diffusion, it should proceed in a vectorial fashion from the adjacent unbleached areas. Conversely, if replenishment involves an intracellular pool of ACA, we should measure an even fluorescence recovery in the middle and the boundaries of the bleached zone (Fig. 2 A). We optimized our FRAP conditions to study the recovery of ACA over a large portion of the plasma membrane for long periods of time. To reduce photodamage, we captured images every 45 s, which precluded us from obtaining quantitative diffusion measurements. As a control for these experiments, we used cells expressing the seven-transmembrane chemoattractant cAR1 fused to YFP, which is uniformly distributed on the plasma membrane and does not localize to intracellular vesicles (Xiao et al., 1997). Differentiated cells were plated at very low density, allowing them to become apolar (Kriebel et al., 2003), and a small region of the cell periphery was bleached. As depicted in Fig. 2 B, we find a dramatic difference in the fluorescence recovery patterns of the cAR1-YFP/car1− and ACA-YFP/aca− cells. Whereas the receptor shows a recovery pattern reminiscent of membrane

Figure 1. ACA is localized on dynamic vesicles that coalesce at the back of polarized cells. (A) Montage of fluorescent images showing maximum intensity projections of a randomly moving ACA-YFP/aca− cell. Also see Video 1. (B) Montage of fluorescent images showing maximum intensity projections of a ACA-YFP/aca− cell chemotaxing toward a micropipette filled with 1 μM cAMP. The asterisk depicts the position of the micropipette. Also see Video 1. (C) 3D reconstruction of z-stack slices showing accumulation of vesicles at the back of a migrating ACA-YFP/aca− cell. F-actin and microtubules control the enrichment of ACA at the back of cells. The association of ACA with intracellular vesicles (Fig. 1) and its rapid, differentiation-dependent replenishment at the cell membrane (Fig. 2) suggest a role for the cytoskeleton in ACA trafficking. To determine the role of the actin cytoskeleton on these processes, we treated differentiated ACA-YFP/aca cells with 5 μM latrunculin A (LatA) and monitored the distribution of the ACA-containing vesicles with time. As we previously reported, LatA-treated cells rapidly round-up and stop moving, and the distribution of ACA on the cell periphery concomitantly becomes uniform (Fig. 3A; Kriebel et al., 2003). However, within 45 min after the addition of LatA, the ACA-positive vesicles disappear and cells show a very bright ACA signal at their periphery (Fig. 3A), a response that we also readily observe when we treat cells with 60 μM LatA for 5 min (not depicted). When LatA-treated cells are photobleached as described in Fig. 2, recovery of the ACA signal now mimics the membrane diffusion pattern of the cAR1 cells, with the side boxes recovering before the middle box (Fig. 3A; LatA-treated cAR1-YFP cells showed an identical response [not depicted]). This treatment also markedly reduced the ability of chemoattractants to stimulate ACA activity (Fig. S1, available online).
Figure 3. F-actin and microtubules control the enrichment of ACA at the back of cells. (A, left) Confocal fluorescent images of ACA-YFP/aca− cells treated with 5 μM LatA for the designated lengths of time. (Inset) Confocal fluorescent image of an ACA-YFP/aca− cell treated with LatA for 45 min showing the bleached area (white) and the side (blue) and middle (red) boxes where the fluorescence recovery is monitored. The graphs depict the recovery of ACA-YFP. Data is presented as a mean of five cells ± SEM. See Fig. 2 B for details. (B, left) Fluorescent images of GFP-α-tubulin/WT cells with or without 60 μM Noco. (Inset) Confocal fluorescent image of an ACA-YFP/aca− cell treated with Noco showing the bleached area. The graphs depict the recovery of ACA-YFP. Data is presented as a mean of five cells ± SEM. See Fig. 2 B for details. (C) Deconvoluted fluorescent image showing ACA-YFP (green) and α-tubulin (red) in fixed ACA-YFP/aca− cells. Also see Video 3. (D) Fluorescent image showing ACA-YFP (green), α-tubulin (red), and DAPI (blue) in fixed ACA-YFP/aca− cells. The position of the MTOC relative to the nucleus was quantified in 63 cells. We find that in 62% of migrating cells the MTOC is localized behind the nucleus and that 76% of cells have either none or one microtubule filament extending to the leading edge. The position of the MTOC was confirmed by labeling centrosomes with anti-γ-tubulin antibodies (not depicted). (E) Fluorescent maximum intensity projections of ACA-YFP/aca− cells (top) or GFP-α-tubulin/WT cells (bottom) chemotaxing to a micropipette filled with 1 μM cAMP in the presence or absence of Noco. The asterisk shows the position of the micropipette. (F) Montage of bright field images of ACA-YFP/aca− cells chemotaxing to a micropipette filled with 1 μM cAMP in the presence or absence of Noco. Also see Video 4. Identical results were observed with WT cells. Videos are available at http://www.jcb.org/cgi/content/full/jcb.200808105/DC1.

Conversely, the chemoattractant-mediated translocation of PH CRAC -GFP to the plasma membrane is unaffected under these conditions (Fig. S2), indicating that LatA treatment had no generalized detrimental effects on cAR1-mediated signal transduction pathways. These findings show that actin-dependent processes are required to maintain the asymmetrical enrichment of ACA at the cell periphery.

We next studied the role of microtubules on ACA vesicle trafficking using Nocodazole (Noco) treatment. For these experiments, we monitored the effects of Noco using cells expressing GFP-α-tubulin (Neujahr et al., 1998) and found that treating cells with 60 μM Noco for 1 h causes a substantial disassembly of the microtubule network (Fig. 3 B). Under these conditions, differentiated ACA-YFP/aca− change their shape, with a majority of cells losing their polarity and appearing round or slightly oblong. Simultaneously, the distribution of ACA-YFP on the cell periphery becomes uniform (Fig. 3 B, inset). Most interestingly, the recovery of the ACA-YFP signal after photobleaching again mimics the membrane diffusion pattern of the cAR1-YFP cells, with the side boxes recovering before the middle box (Fig. 3 B; Noco treatment had no effect on the fluorescent recovery of cAR1-YFP cells [not depicted]).

These findings indicate that an intact microtubule network is required for the asymmetrical enrichment of ACA at the cell periphery.

We next set out to determine if ACA vesicles are associated with microtubules. We fixed fully differentiated ACA-YFP/aca− cells, stained them with an anti–α-tubulin antibody, and performed deconvolution microscopy. As expected, we find that the ACA vesicles align on microtubules (Fig. 3 C and Video 3, available at http://www.jcb.org/cgi/content/full/jcb.200808105/DC1). Upon further analyses, we discovered that the front of polarized cells is virtually devoid of ACA vesicles and microtubules, although ACA is clearly present around the entire cell periphery and may appear spotty especially at the leading edge. Indeed, quantitative analyses show that in 62% of migrating cells (n = 63) the microtubule organizing center (MTOC) is localized behind the nucleus where an intricate microtubule network emanates toward the back of every cell. In contrast, 76% of the cells have either none or one microtubule filament extending to their leading edge (Fig. 3 D). These findings suggest that the microtubule network is organized to promote the trafficking of cargo, including ACA, to and from the back of highly polarized cells. In support of this notion, we find that Noco-treated ACA-YFP/aca− cells exposed to a chemoattractant-containing micropipette polarize and migrate rapidly but show a significant defect.
We then used the impermeable dye FM4-64 to assess the role of endocytic trafficking in the dynamic distribution of ACA. This dye fluoresces only when incorporated in the plasma membrane and, once internalized, it becomes trapped in intracellular vesicles, thereby representing a useful tool to visualize endocytosis (Vida and Emr, 1995). Differentiated ACA-YFP/aca− cells were incubated with FM4-64 under conditions designed to minimize the contractile vacuoles (see Materials and methods) and examined at various time points by confocal microscopy. Under these conditions, FM4-64 labeling becomes restricted to small endosome-like compartments (Zhu and Clarke, 1992; Aguado-Velasco and Bretscher, 1999). As expected, we observe strong plasma membrane labeling 1 min after the addition of FM4-64, which readily internalizes to label intracellular compartments after 30 min (Fig. 4 B). Under these conditions, we consistently see colocalization of the dye with ACA-YFP vesicles in a central perinuclear area (Fig. 4 B). Yet, distinct red (FM4-64) and green (ACA-YFP) vesicles are also present throughout the polarized, migrating cells (Fig. 4 B, Merge and Slice Merge). We also observe portions of the ACA-YFP compartment at the back of cells that does not colocalize with FM4-64, both at the cell

### Figure 4. ACA vesicles are not targeted to lysosomes and require proper assembly of clathrin for trafficking.

(A) Montage of confocal fluorescent images depicting Dextran–Alexa 568 (red) and ACA-YFP (green) distribution in ACA-YFP/aca− cells. (B) Spinning disk and confocal fluorescent images of ACA-YFP/aca− cells labeled with FM4-64 (red) for 1 and 30 min and ACA-YFP (green). In the top six images, maximum intensity projections are presented. The bottom two images represent confocal slices taken from the maximum intensity projection of the merge. (C) Images of clc− and chc− cells chemotaxing to a micropipette containing 1 μM cAMP. (D) Confocal fluorescent images of ACA-YFP/aca− and ACA-U-YFP/clc− cells colabeled with lysotracker red. The asterisk represents the position of the micropipette.

in their ability to enrich ACA-YFP at their back and to align in a head-to-tail fashion during chemotaxis (Fig. 3, E and F; Video 4; and Table S1). These findings show that microtubules are essential for ACA-containing vesicles to accumulate at the back of polarized cells and for streaming during chemotaxis.

**ACA vesicles are not targeted to lysosomes and require proper assembly of clathrin for trafficking**

To gain more insight into the nature of the ACA-labeled vesicles, we first performed colocalization studies with lysosomal markers. Fully differentiated ACA-YFP/aca− cells were incubated with labeled Dextran–Alexa 568 or BSA–Alexa 568 for 1 h, extensively washed, and plated on coverslips, and the YFP and Alexa signals were visualized by confocal microscopy (Hacker et al., 1997). We found no colocalization between ACA vesicles and the endocytosed Dextran–Alexa 568 or BSA–Alexa 568 (Fig. 4 A and not depicted), confirming and extending previous studies using lysotracker (Kriebel et al., 2003). These findings establish that ACA vesicles are not associated with lysosomes.

We then used the impermeable dye FM4-64 to assess the role of endocytic trafficking in the dynamic distribution of ACA. This dye fluoresces only when incorporated in the plasma membrane and, once internalized, it becomes trapped in intracellular vesicles, thereby representing a useful tool to visualize endocytosis (Vida and Emr, 1995). Differentiated ACA-YFP/aca− cells were incubated with FM4-64 under conditions designed to minimize the contractile vacuoles (see Materials and methods) and examined at various time points by confocal microscopy. Under these conditions, FM4-64 labeling becomes restricted to small endosome-like compartments (Zhu and Clarke, 1992; Aguado-Velasco and Bretscher, 1999). As expected, we observe strong plasma membrane labeling 1 min after the addition of FM4-64, which readily internalizes to label intracellular compartments after 30 min (Fig. 4 B). Under these conditions, we consistently see colocalization of the dye with ACA-YFP vesicles in a central perinuclear area (Fig. 4 B). Yet, distinct red (FM4-64) and green (ACA-YFP) vesicles are also present throughout the polarized, migrating cells (Fig. 4 B, Merge and Slice Merge). We also observe portions of the ACA-YFP compartment at the back of cells that does not colocalize with FM4-64, both at the cell
ACA trafficking requires de novo ACA synthesis. (A) Western analysis showing the expression of ACA-YFP from ACA-YFP/aca+ cells or cAR1-YFP from cAR1-YFP/car1/3+ cells in the presence or absence of 400 μM CHX. Similar findings were observed when we monitored endogenous levels of ACA in WT cells. See Materials and methods for details. Representative data of at least three independent experiments are shown. (B) Fluorescent maximum intensity projections of ACA-YFP/aca+ cells chemotaxing to a micropipette filled with 1 μM cAMP in the presence or absence of CHX (1-h treatment). The asterisk represents the position of the micropipette. (C, inset) Confocal fluorescent images of ACA-YFP/aca+ or cAR1-YFP/car1/3+ cells treated with CHX (1 h) showing the bleached area (white) and the side (blue) and middle (red) boxes where the fluorescence recovery is monitored. The graphs depict the recovery of ACA-YFP and cAR1-YFP. See Fig. 2 B for details. (D) Bright field images of ACA-YFP/aca+ cells chemotaxing to a micropipette containing 1 μM cAMP in the presence or absence of CHX (1-h treatment). Also see Video 5. Identical results were observed with WT cells. (E, top) Confocal fluorescent images of ACA-YFP/aca+ or cAR1-YFP/car1/3+ migrating cells before and after complete bleach. The numbers represent the time (in seconds) after the bleach. Also see Video 6. The graphs depict the total fluorescent recovery of ACA-YFP or cAR1-YFP from the entire cell under various conditions. Data are presented as a mean of five cells ± SEM. It is the short maturation time of YFP that has allowed us to visualize the quick recovery of ACA. Cells expressing ACA-GFP show no recovery after total bleaching (not depicted). (F, right) Radiographs depicting the incorporation of 35S-Translabel into ACA-YFP or cAR1-YFP from the entire cell under various conditions. Data are presented as a mean of five cells ± SEM. We next turned our attention to cells lacking clathrin. Clathrin is a triskelion made of three clathrin heavy chains (CHCs) and three clathrin light chains (CLCs; Brodsky et al., 2001). Dictyostelium chc−/H11002 cells exhibit classical endocytosis defects (O’Halloran and Anderson, 1992; Ruscetti et al., 1994). In contrast, clc− cells show no such defects and have normal triskelion structures, but exhibit less clathrin structures at the membrane and more in the cytosol. These findings suggest that the CLCs are required to optimally assemble clathrin at the plasma membrane (Wang et al., 2003). We found that cells lacking either the CHCs or the CLCs are able to properly develop and to chemotax to a point source of chemotractant, a finding reported by others for chc− cells (Wessels et al., 2000; Table S1). Interestingly, both cell lines exhibit significant streaming defects (Fig. 4 C). We attempted to transfect chc− and clc− cells with the ACA-YFP expression plasmid on several occasions but were not successful in generating stable cell lines. We reasoned that overexpression of a catalytically active ACA might be detrimental to these cells. We therefore used a mutant of ACA that lost the capacity to be activated by G proteins (ACA-U-YFP) but retains a normal cellular distribution pattern (Kriebel et al., 2003). Although we were unable to obtain chc− cells expressing ACA-U-YFP, we successfully generated stable ACA-U-YFP/clc− cells. We found the distribution of ACA-U-YFP to be aberrant in these cells, with a dramatic loss of plasma membrane staining and loss of enrichment at the back and a significant accumulation of ACA-YFP in large intracellular vesicles that costain with lysotracker (Fig. 4 D) or Dextran–Alexa 568 (not depicted). These large compartments were also readily observed in untransfected clc− cells (unpublished data). We conclude that the loss of CLCs leads to the mislocalization of ACA and aberrant streaming. Because we were unable to study ACA distribution...
in chc− cells, it is impossible to for us to definitively address the role of clathrin-mediated endocytosis in ACA vesicle trafficking. In any case, our findings using chc− cells clearly establish that proper clathrin assembly is required for normal cellular distribution of ACA.

ACA trafficking requires de novo ACA synthesis

To assess the role of protein synthesis in the cellular distribution of ACA, we treated ACA-YFP/acα− cells with cycloheximide (CHX) and subjected them to FRAP analyses. It has previously been shown that CHX treatment does not alter the ability of Dictyostelium cells to sense chemoattractant gradients or to uptake membrane by endocytosis; yet it does inhibit the ability of Dictyostelium cells to migrate directionally (Clotworthy and Traynor, 2006). We therefore closely observed the effect of CHX over time. We first monitored the expression level of ACA-YFP using Western analysis and found that it is significantly decreased after CHX treatment (Fig. 5 A). An identical treatment did not alter the expression level of cAR1-YFP (Fig. 5 A).

We observed that ACA-YFP cells treated with CHX for 1 h, which shows a mild decrease in ACA-YFP expression, exhibit a significant and specific defect in their ability to enrich ACA-YFP at their back, the expression of ACA-YFP at the front of cells remains unchanged (Fig. 5 B, Table S1, and not depicted). Under these same conditions, the fluorescence recovery of the ACA-YFP signal after photobleaching is also altered and mimics the membrane diffusion pattern of the cAR1-YFP cells, with the side boxes recovering before the middle box (Fig. 5 C). CHX-treated cells were then exposed to a chemoattractant gradient. We find that CHX treatment does not affect the ability of cells to polarize and migrate toward the micropipette, although they consistently move more slowly (Table S1). However, as expected, CHX-treated cells display severe streaming defects (Fig. 5 D and Video 5), similar findings were obtained after a 30-min CHX treatment, available at http://www.jcb.org/cgi/content/full/jcb.200808105/DC1). Together, these findings establish that ACA synthesis is required to maintain its enrichment at the back of cells and for streaming. Although we certainly cannot rule out that the expression of other proteins is also affected by CHX treatment, the fact that we observe dramatic effects in spite of a higher methionine and cysteine content, compared to other proteins, underscores the importance of ACA synthesis during streaming.

The extent of ACA synthesis was also observed in real time after total bleaching, a process in which the entire cell is bleached. When differentiated and polarized ACA-YFP/acα− cells are subjected to such a treatment, the fluorescent signal quickly and significantly recovers (Fig. 5 E). As expected from our findings, we observed that CHX treatment abolishes the recovery of ACA-YFP and that cAR1-YFP/carβα− cells show no significant fluorescence recovery under all conditions tested (Fig. 5 E).

We performed [35S]methionine/cysteine labeling experiments to gain insight into the rate of ACA de novo synthesis. We added [35S]methionine/cysteine to fully differentiated ACA-YFP cells and at specific time points assessed the 35S content in ACA immunoprecipitates. We measured [35S]methionine/cysteine incorporation in a specific band of 170 kD (Fig. 5 F), which comigrates with pulled down ACA-YFP and is missing in wild-type (WT) cells (not depicted). Under these conditions, incorporation of [35S]methionine/cysteine in ACA-YFP is rapid and robust. It is detected at the earliest time point collected (3.75 min) and peaks at 30–60 min. In contrast, cAR1-YFP cells show trace levels of [35S]methionine/cysteine incorporation (Fig. 5 F) in spite of a higher methionine and cysteine content, compared with ACA-YFP.

ACA vesicles are distributed within multivesicular bodies (MVBs) that are shed during migration

Upon closer examination of ACA-YFP/acα−, we found that actively migrating cells leave behind membranous structures rich in ACA (Fig. 6, A and B; and Videos 7 and 8, available at http://www.jcb.org/cgi/content/full/jcb.200808105/DC1). Uchida and Yumura (1999) originally coined the term “cellular tracks”
when they observed that *Dictyostelium* cells leave tracks fluorescently labeled with concavalin A. They observed that chemotaxis-competent cells often migrate on these tracks and proposed that they help cells migrate directionally. To gain more insight into this, we measured the amount of ACA-containing tracks in WT and Noco- or CHX-treated cells. As both treatments hamper the asymmetrical delivery of ACA at the back of cells and the ability of cells to stream, we reason that they would also lead to the generation of fewer tracks. We monitored >160 actively migrating cells for each condition and find that either treatment significantly reduces the amount of ACA-positive trails by >50% compared with control (Fig. 6 C and see Fig. S3 for details). The expression level of ACA-YFP in control and Noco- or CHX-treated cells was identical as monitored by Western and FACS analyses (unpublished data). Together, these findings suggest that the ACA-containing tracks act as directional cues during chemotaxis.

We used hyperbaric freeze EM to obtain high quality ultrastructural information on the back of polarized migrating cells and on the nature of the extracellular, ACA-positive structures proximal to it. Fig. 7 A depicts a typical cell with a clearly polarized ultrastructure, a centrally located nucleus, and various types of vesicles concentrated toward one end of the cell, which we presume is the back. We used immunogold EM to visualize the distribution of ACA. As presented in Fig. 7 (B–I), we found gold labeling to be particularly dense at the plasma membrane and in extracellular as well as intracellular vesicles. Quantification of gold particles revealed a sevenfold enrichment at the plasma membrane relative to the nuclear membrane (4.1 ± 0.38 vs. 0.73 ± 0.13 gold particles/μm, respectively). Intracellularly, the gold labeling was particularly dense in three specific locations: on highly tubular, membranous structures (Fig. 7 B), on densely packed structures (Fig. 7 C), and on MVBs (Fig. 7, D and E). Although, we do not know the exact nature of the highly tubular structures, we envision that they are part of the biosynthetic pathway that feeds into the vesicular pool of ACA. The extent of MVBs labeling was striking as it occurred on 24% of identified MVBs. We did not observe labeling of lysosomal compartments, which confirmed our colocalization studies with ACA-YFP.
and Dextran–Alexa 568 (Fig. 4 A). Remarkably, we observed labeling on an extensive network of extracellular vesicles both at the back of cells, proximal to the plasma membrane (Fig. 7, F and G), and as trails (Fig. 7, H and I), presumably corresponding to the ACA-positive trails we observe in our live imaging of migrating ACA-YFP cells (Fig. 6 and Videos 7 and 8).

Interestingly, we also routinely observed FM4-64 labeling at the back of cells that colocalized with ACA-YFP (Fig. 4 B). As this occurred very early after FM4-64 addition, we reason that the FM4-64 is actually labeling accumulated extracellular membrane present at the back of cells. Together, these findings establish that ACA is present at the plasma membrane and on complex intracellular vesicles, which appear to be specifically released at the back of cells.

Discussion

Our findings show that vesicle trafficking is required for the asymmetrical distribution of ACA in polarized Dictyostelium cells. We show that the distribution of ACA at the back of cells results from an accumulation of vesicles that mainly arise from a biosynthetic pathway and that intact microtubule and actin networks are required to maintain this enrichment. Interestingly, EM analyses reveal that ACA is found on MVBs that accumulate at the back of cells where they are poised to release their contents as exosomes and propagate chemotactic signals. Although we do not know the exact mechanism by which ACA is trafficked to MVBs, our findings clearly bring forward a pathway that is distinct from the canonical pathway where sorting vesicles, is dramatically inhibited compared with untreated cells. It has been proposed that polymerized actin amplifies phosphatidylinositol-3-kinase (PI3K) activity after chemoattractant stimulation (Weiner et al., 2002; Sasaki et al., 2004). As ACA activity is PI3K-dependent, this raises the possibility that the effect of LatA on ACA activity could be mediated through reduced PI3K activity. However, we find significant phosphatidylinositol (3,4,5)-trisphosphate generation in LatA-treated cells (Parent et al., 1998; this study). We therefore conclude that the strong inhibition of ACA activity in LatA-treated cells is not related to effects on PI3K. Indeed, we have previously shown that PI3K activity regulates ACA activation, but not its cellular distribution (Comer and Parent, 2006). Rather, our findings suggest that the activatable pool of ACA is restricted to the vesicular pool of the enzyme. Interestingly, we reported a constitutively active mutant of ACA is aberrantly distributed in cells, showing a dramatically reduced enrichment of ACA at the back of cells and a higher number of internal vesicles, ultimately giving rise to streaming defects when expressed in aca− cells (Kriebel et al., 2003). These findings suggest that there is a relationship between the cellular distribution of ACA and its catalytic activity. It has previously been shown that the highest peak of Dictyostelium ACA activity resides in a sedimentable light membrane fraction mainly composed of small vesicles (Hintermann and Parish, 1979). In addition, Maeda and Gerisch (1977) have shown that intracellular vesicles and vacuoles change in numbers in response to cAMP pulses and extensively fuse with the plasma membrane. This led them to propose that exocytosis is responsible for the secretion of cAMP in Dictyostelium. However, Dinauer et al. (1980) showed that cAMP is immediately secreted after its synthesis and proposed that cAMP is not stored in vesicles. Our findings clearly show the existence of an asymmetrically distributed vesicular pool of ACA in polarized cells that is responsible for the alignment of cells into streams, presumably through the release of cAMP at the back of the cell. Whether or not cAMP is stored in vesicles for release...
at a later time or is synthesized in vesicles and then immediately released cannot be discerned by our data. However, our results are compatible with both options.

Microtubule cortical capture plays a key role in controlling vesicle trafficking, although the underlying mechanistic basis for this is not yet defined (Gundersen et al., 2004). In this context, the actin-based motor myosin V has been shown to be involved in mediating the movement of cargo from microtubules to actin filaments at the cell cortex (Wu et al., 2006). We studied Dictyostelium cells lacking myosin J (MyoJ), which shares homology with class V and IX myosins (Hammer and Jung, 1996; Peterson et al., 1996). Cells lacking MyoJ showed significant streaming defects and mislocalization of ACA after 5 h of development. However, these defects were completely reversible by 7 h of development (unpublished data), suggesting that the MyoJ-null cells exhibit a developmental delay or that redundant components expressed later can foster the delivery of ACA vesicles to the back of cells. We also find that polarized Dictyostelium cells have an extensive microtubule network at their back, which originates from a MTOC that is positioned behind the nucleus. Remarkably, the leading edge of these cells is virtually devoid of microtubule fibers. We envision that this architecture, which is also observed in neutrophils and migrating lymphocytes, is present to preferentially accommodate cargo delivery to the back of cells (Ratner et al., 1997; Eddy et al., 2002). In contrast, in slow moving fibroblasts, the MTOC is positioned in front of the nucleus and microtubules primarily extend to the front of these cells during scratch wounding–mediated migration (Kupfer et al., 1982; Gundersen and Bulinski, 1988). We predict that this fundamental difference between cell types underlies distinct requirements for cargo delivery to the front and back of cells in amoeboid (Dictyostelium, neutrophils, and lymphocytes) versus mesenchymal (fibroblasts) migration. Interestingly, as previously observed in neutrophils, we found that a fully functional microtubule network is not required for chemotactic migration in Dictyostelium cells (Niggli, 2003; Xu et al., 2005). In neutrophils, it does, however, enhance the activity of Rho kinase, which is involved in controlling actomyosin-dependen back contractility. It therefore appears that in both Dictyostelium and neutrophils, microtubules regulate “backness” events.

Our findings have general implications for chemoattractant delivery and group migration. Secreting vesicles could act as tracks, allowing cells to follow a path left by a leading cell. Many cells have been shown to secrete vesicular components, including exosomes. For instance, B cells and dendritic cells secrete exosomes that carry major histocompatibility complex class I and II (Rapoport et al., 1996; Zitvogel et al., 1998). Activated platelets secrete exosomes by fusion of α-granules and endothelial cells release TNFR1 from exosome-like vesicles to modulate TNF bioactivity (Heijnen et al., 1999; Hawari et al., 2004). Interestingly, it has recently been shown that T cells store the chemokine RANTES in small vesicles that are distinct from lysosomal secretory granules and release it after T cell receptor stimulation (Catalfamo et al., 2004); this situation is analogous to what we report here. Finally, vesicle shedding has been observed in a wide variety of tumor cells (Dolo et al., 1998; Taverna et al., 2003). In particular, invasive melanoma cells release cell fragments in a migration-dependent manner, and the tracks left behind have been proposed to represent zones of facilitated invasion of neighboring cells, allowing the migration of cells in chains or streaming (Mayer et al., 2004). In this context, it will be interesting to determine if the release of chemoattractant in vesicles also plays a role in the paracrine loop regulating the comigration of macrophages and carcinoma cells during metastasis (Yamaguchi et al., 2005). The findings reported here suggest that this fascinating mode of cell–cell communication appeared early during evolution.

Materials and methods

Materials

The GFF–α-tubulin constructs were provided by A. Muller-Taubenberger (Ludwig Maximilians University Munich, Munich, Germany) and G. Gerisch (Max Planck Institute of Biochemistry, Martinsried, Germany). T. Jin (National Institute of Allergy and Infectious Diseases, National Institutes of Health, Rockville, MD) provided the cAR1-YFP construct. R. Graf (University of Potdam, Postdam-Golm, Germany) provided the γ-tubulin antibody. J. Hammer (National Heart, Lung, and Blood Institute, National Institutes of Health, Bethesda, MD) provided the myosin/c-myosin and myoJ cells, and T. O’Halloran (University of Texas at Austin, Austin, TX) provided the cdc- and chc- cells. The α-tubulin antibody, developed by J. Frankel and E.M. Nelsen, was obtained form the Developmental Studies Hybridoma Bank developed under the auspices of the National Institute of Child Health and Human Development and maintained by the University of Iowa.

Cell culture and differentiation

WT [AX], ACA-YFP/aca–, and cAR1-YFP/car1/3– cells were grown in shaking cultures to ~4 × 10⁶ cells/ml in HL5 media (Kriebel et al., 2003). They were harvested by centrifugation, washed once in developmental buffer (DB; 5 mM Na₂HPO₄, 5 mM NaH₂PO₄, pH 6.2, 2 mM MgSO₄, 200 μM CaCl₂), and finally resuspended in DB at 2 × 10⁶ cells/ml. To allow differentiation, the cells were shaken at 100 rpm for 4–7 h with repeated pulses of 75 nM cAMP (Devreotes et al., 1987; Parent and Devreotes, 1996a). The cells were then processed according to the assay performed.

Confocal fluorescence microscopy

Cell preparation. Cells were differentiated as described in the previous paragraph. A 200-μl sample of cells was removed, centrifuged, resuspended in 200 μl of phosphate buffer (PB; 5 mM Na₂HPO₄ and 5 mM NaH₂PO₄, pH 6.2, 2 mM MgSO₄, and 200 μM CaCl₂), and finally resuspended in DB at 2 × 10⁶ cells/ml. To allow differentiation, the cells were shaken at 100 rpm for 4–7 h before adding 1 ml PB to fill the chamber.

Confocal microscopy detailing ACA-YFP distribution in cells. ACA-YFP–/aca– cells were prepared for microscopy and observed with a microscope (Axiovert 200; Carl Zeiss, Inc.) equipped with a confocal system (UltraView ERS; PerkinElmer) with a spinning dish head (Yokogawa) and a camera (Orca ER; Hamamatsu). Single plane images and z stacks were taken using 63 and 100x plan neofluor objectives (Carl Zeiss, Inc.) and z stacks were arranged in maximum intensity projections.

Confocal microscopy with dextran–Alexa and lysotracker. Cells were incubated with 10 mM dextran–Alexa 568 at 10,000 MW [Intravenous] for 1 h or with 4 μM lysotracker red DND 99 [Intravenous] for 30 min. The cells were washed and plated on chambered slides. Confocal images were taken with a microscope (510 LSM; Carl Zeiss, Inc.) using a 63x plan neofluor objective.

Confocal microscopy with FMA-64. Cells were pretreated with 0.1 M sorbitol in PB before the addition of FMA-64 to reduce the formation of contractile vacuoles, a specialized organelle designed to expel water from Dictyostelium cells that is extensively labeled with FMA-64. 2 μM FMA-64 was added to cells for 30 min. Both 0.1 M sorbitol and FMA-64 were present with the cells while imaging. Z stacks encompassing the entire cells were taken using the confocal system equipped with a spinning dish head and a camera. FMA-64 and ACA-YFP were visualized in red and green channels, respectively.
Vegetative, 5-h differentiated nonpolar, 5-h differentiated polar nonmigrating, and polar-migrating ACA-YFP/aca or car1-YFP/car1/3 cells were spotted onto chamber slides and allowed to adhere for 5 min. 5-h differentiated nonpolar cells were obtained by diluting (1:100-1:500) pulsed cells before spotting them on a chamber slide as previously described (Kriebel et al., 2003). Polar, nonmigrating cells were obtained by allowing the diluted cells to slowly polarize on the chamber slide. This occurs secondary to the buildup of cAMP, which is spontaneously released. Polar-migrating cells were obtained by spotting 5-h differentiated cells 10-fold more concentrated. To visualize the entire cell on the microscope, cells were flattened with a 4-mm thick slice of agarose gel so that the entire cell body was within a height that could be visualized and bleached by a wide-open pinhole of 5 μm. The bleach box was expanded to include a portion of the top and the bottom membrane to minimize the contribution of diffusion from above and below the bleach box. A section of the cell periphery in zoom 3 was exposed to two iterations of saturating 488-nm laser light inducing a partial bleach. A series of single plane (5 μm) time-lapse images were taken using a 63 × plan neofluor of saturating 488-nm laser light inducing a partial bleach. A single image taken just after the bleach was used to determine the bleach level. Each subsequent image was taken every 45 s after bleaching and used to determine the recovery of fluorescence over time. All image processing was done using the LSM 5.0 software (Carl Zeiss, Inc.). The fluorescent intensity values of each ROI over time was normalized so that the starting value was 100% and the value after bleaching was 0%. The normalized fluorescent intensity values of all ROIs were obtained from five independent cells, averaged and plotted over time. FRAP was measured in migrating cells using the same conditions. However, we only monitored the fluorescence recovery at a single ROI located at the center of the bleached box. The side bleach ROIs were left out because the dynamic nature of the cell periphery in migrating cells made the location of these areas difficult to discern from frame to frame. However, the center area was easily identifiable because it was always at the apex of the curve of the plasma membrane at the back of the cell. This center ROI was redrawn on the corresponding position of each cell that moved. The data were processed as described. FRAP with complete bleaching was performed by bleaching the three bleach ROIs at each of three locations of saturating 488-nm wavelength, 45 s apart. Only one ROI was used to monitor fluorescence and it encompassed the entire cell. Fluorescent intensity values were obtained, normalized, averaged, and graphed as described.

FRAP with cytoskeletal disruption and protein synthesis inhibitors. 5 μM LatA (for 45–60 min; Invitrogen), 30–60 μM Noc (for 60 min; EMD), or 200–400 μM CHX (for 60 min; Sigma-Aldrich) was added to cells on a chamber slide. Gel slabs soaked in double the designated concentration of drug for 2 h were carefully layered on top of the treated cells. FRAP analyses were performed as described.

Deconvolution microscopy ACA-YFP/aca cells were differentiated, plated, and allowed to polarize as described. They were quickly fixed at room temperature for 10 min in ice-cold methanol (−20°C) and 1% glutaraldehyde (0.01% Triton X-100) in 15 mM Pipes/1 mM EGTA. After blocking in 10% FBS in PBS, the cells were incubated with an anti-α-tubulin antibody (1:200; Developmental Studies Hybridoma Bank) followed by an anti–mouse IgG1 antibody conjugated to Alexa 568 (Invitrogen). YFP and Alexa 568 images were taken with a DeltaVision system (Applied Precision, LLC) using a 63× objective. Deconvolution was performed with DeltaVision software and 3D reconstructions were made with Imaris software (Bitplane AG). The quantification studies were done with the same fixative and staining protocol. Cells were scored for location of the MTOC with respect to the nucleus (stained with DAPI) and the presence of microtubules going to the leading edge of the cell.

Quantification of the cell track fluorescence Starved and pulsed cells were plated on 3-mm plates in 1 ml PB in the presence of 200 μM CHX or 60 μM Noco (or appropriate control solvents) at room temp for 1 h. Cells were harvested using a cell scraper, pelleted and resuspended in 500 μl PB containing the appropriate drug conditions, spotted on chamber slides, allowed to attach, and covered with 1.5 ml PB containing the appropriate drug or control. The cells were allowed to migrate toward a micropipette filled with 10 μM cAMP for ~20 min. A 1-μm confocal slice focused on the tracks at the bottom of the chamber was taken every 10 s using a microscope with a 488-nm laser and a 63× plan neofluor objective. These images were taken in conjunction with differential interference contrast images. Track fluorescence was obtained using Vision-Mac version 4.0.10 software (BioVision Technologies). Background fluorescence values were taken from starting images and subtracted from all images in a series. Segments were drawn around fluorescent debris in the initial image and transferred to the final image of the series (see Fig. S3 for details). New segments were drawn on the final image of the series around fluorescent tracks excluding debris detected by segments from the initial image. Cell track fluorescence was determined by measuring the fluorescence in segments around tracks. Cells were counted manually as they entered the field of view. Fluorescent 1-μm confocal images and corresponding differential interference contrast images were merged using the color join command in iVision to create images of cells in Fig. S3. Fluorescent intensity in segments marking debris was set to 0 debris in the merged images to emphasize only the tracks left behind by migrating cells (Fig. S3).

Chemotaxis assay The chemotaxis assays were performed as previously described (Kriebel et al., 2003). In brief, 5–7-h differentiated cells were plated on chambered cover slides as described previously (Kriebel et al., 2003). Chemotactic gradients were generated using a microinjector (Eppendorf) using micropipettes filled with 1 μM cAMP. The micropipette was placed in chambered cover slides and images were captured at specified times.

ACA activity and cytосolic regulator of ACA (CRAC) translocation assays ACA and CRAC translocation assays were performed as previously described (Kriebel et al., 2003; Comer et al., 2005).

32P metabolic labeling 5-h developed cells were placed directly into 35-mm Petri dishes (10 × 106 cells/dish). After the cells had adhered for 5 min, 420 μCi of TRANS32P-Label (MP Biomedical) was added to each plate. One plate was harvested for each designated time point, the cells were spun, resuspended in IP buffer (40 mM Tris-HCl, pH 8.0, 2 mM EDTA, 50 mM NaCl, and 1% CHAPS) and Complete protease inhibitor cocktail (Roche), and solubilized for 1 h on ice. After solubilization, 100 μl of a 50/50 protein A sepharose CL-4B (GE Healthcare)/IP buffer slurry was added to each sample and incubated using a rotator for 1 h at 4–8°C to preclear the lysate. The protein A sepharose slurry was removed by centrifugation and 7 μl of anti-GFP rabbit polyclonal (BD) was added per milliliter of lysate and incubated on a rotator overnight at 4–8°C. 100 μl of a 50/50 protein A sepharose slurry was added and incubated for 2 h at 4–8°C to precipitate ACA-YFP or car1-YFP. Samples were washed four times with 1 ml IP buffer. The precipitated proteins were released from sepharose beads by adding laemmli buffer and boiling for 10 min (Laemmli, 1970). The resulting samples were run using the Criterion gel system (BioRad Laboratories) using a 4–20% Tris-HCl gel; the gel was dried and the bands were visualized with Biomax MR film (Kodak).

Immunoblotting CHX was added to 5-h differentiated cells in shaking flasks containing 2 × 107 cells/ml and pulsed for an additional 2 h. 2.7 × 106 cells were harvested at 0, 30, 60, and 120 min and resuspended in 100 μl Laemmli buffer (Laemmli, 1970). Whole cell lysates were subjected to a 4–20% Tris-HCl SDS-PAGE analysis using the Criterion gel system and transferred to Immobilon-P (Millipore). The Immobilon-P was blotted with anti-GFP monoclonal antibody (1:5,000; Babco) and detection was performed by chemiluminescence using a donkey anti-mouse horseradish peroxidase–coupled antibody (1:5,000; GE Healthcare) and the ECL Western blotting detection reagents (GE Healthcare).

EM For immunogold EM staining, cells were differentiated and prepared for microscopy as described. Samples were immunostained for EM using a modification of the method used in Polshchuk et al. (2000). Cells were fixed at room temperature for 15 min in 1% formaldehyde, 0.1% glutaraldehyde, and 0.1% digitonin in 15 mM Pipes/1 mM EGTA, followed by a wash in PBS. Afterward, the cells were postfixed in 1% osmium tetroxide in PBS. For sections, the cells were embedded in Epon and ultrathin sections were cut and examined.
by 15 min in 1% formaldehyde. After blocking in 50 mM NH4Cl, 0.1% digitonin, and 1% BSA in PBS, the cells were incubated with an anti-GFP antibody (1:500; Abcam) in block solution overnight at 4°C followed by anti-rabbit Fab fragments conjugated to Nanogold particles (1.4-nm particle; Nanoprobes). Staining was enhanced for 7 min with Gold-Enhance (Nanoprobes) made with one part component A, one part component B, one part component C, and three parts PBS. Afterward, the samples were stained with osmium and embedded in epox. Images were taken with a transmission microscope (H-7000; Hitachi High Technologies America, Inc.).

Hyperbaric freeze EM
Differeniated cells were spotted on 50-μm-thick sapphire discs (3 mm in diameter; BAL-TEC) and allowed to adhere. The cells were fixed with 2% formaldehyde and 2% glutaraldehyde in PB for 15 min (just before they started to stream). After three rinses in PB, the discs were dipped into either 5% Ficoll (MW: 70,000) or 10% FCS in PB and sandwiched between two flat aluminum specimen carriers with a Chien slot grid (Ted Pella) as a spacer for high pressure freezing (Reipert et al., 2004). The samples were frozen in a high-pressure freezer (HPM10; BAL-TEC) at a pressure of ~2,000 bar. The frozen samples were transferred to an AFS freeze-substitution system (Leica) and subjected to freeze substitution in 1.0% osmium tetroxide in acetone at −90°C for 3 d and then slowly warmed up (5°C per hour) to 20°C. After several rinses in acetone, the samples were infiltrated with mixtures of epon-aradite (Ted Pella) resin and acetone as follows: 1:2 for 2 h, 1:1 for 4 h, 2:1 overnight, and in pure resin for 24 h with two changes. Finally, the discs were placed into the flat-bottomed BEEM capsules for polymerization at 60°C for 1 d. After polymerization, the sapphire discs were separated from the resin blocks with the aid of liquid nitrogen vapor. Ultra thin sections (~80 nm) were cut on Reichert Ultracut E Microtome (American Optical) and collected on copper slot grids. Sections were counter-stained with uranyl acetate and lead citrate and examined under a transmission electron microscope (CM120; FEI; equipped with an image filter [GIF10; Dino , V. , A.
