Key words Sun: helioseismology – Sun: interior

1 Introduction

Time-distance helioseismology (Duvall et al. 1993) is a technique for measuring the time for waves to travel from one point on the solar surface to another. These wave travel times are affected by advection by subsurface flows. Inferences of plasma flows based on observed travel times depend critically on the ability to accurately model the effects of subsurface flows on time-distance measurements. We present a Born-approximation based computation of the sensitivity of time-distance travel times to weak, steady, inhomogeneous subsurface flows. Three sensitivity functions are obtained, one for each component of the 3D vector flow. We show that the depth sensitivity of travel times to horizontally uniform flows is given approximately by the kinetic energy density of the oscillation modes which contribute to the travel times. For flows with strong depth dependence, the Born approximation can give substantially different results than the ray approximation.

2 Sensitivity functions

In this section we use the Born approximation to obtain the linear sensitivity of travel times to weak and steady subsurface flows. We are looking for kernels $K = (K_x, K_y, K_z)$ which satisfy

$$\delta \tau(x_1, x_2) = \iiint \, dr \, K(r; x_1, x_2) \cdot v(r),$$

where the integration variable $r$ runs over the entire volume of the solar model and $v = (v_x, v_y, v_z)$ is the flow field. Throughout this paper we will denote three-dimensional position vectors by $r = (x, z)$ where $x = (x, y)$ is the hor-
izontal position vector and $z$ is depth. The travel-time difference between surface locations $x_1$ and $x_2$ is denoted as $\delta t(x_1, x_2)$ and defined by

$$\delta t(x_1, x_2) = \tau_s(x_1, x_2) - \tau_s(x_2, x_1),$$

where $\tau_s(x_1, x_2)$ is the one-way travel time, as defined by GB02, from $x_1$ to $x_2$.

Following GB02 and B04, we begin by considering damped and driven solar oscillations with a displacement field $\xi$ that obeys, to lowest order in the flow velocity $v$,

$$[\mathcal{L}_0 + \delta \mathcal{L}] \xi = S,$$

with the wave equation operator in the absence of flows, $\mathcal{L}_0$ (e.g. Lynden-Bell & Ostriker 1967), given by

$$\mathcal{L}_0 \xi = \rho_0 \ddot{\xi} - \nabla [\gamma p_0 \nabla \cdot \xi + \xi \cdot \nabla p_0] + (\nabla \cdot \xi) \nabla p_0 + \rho_0 \partial_t (\Gamma \xi),$$

where $\rho_0$, $p_0$, and $\gamma$ are the background density, pressure, and ratio of specific heats. We use solar model S (Christensen-Dalsgaard et al. 1996). The damping operator is $\Gamma$ (B04). In Eq. (4) we have used the Cowling approximation and also neglected the variation of the gravitational acceleration with depth. We have also neglected the Coriolis force. The source function $S$ is intended to represent the driving of oscillations by near-surface turbulent convection. In order to compute the covariance of the waveform $\xi$ we only need the covariance of the source $S$. We choose to use the source covariance described by B04.

The first-order perturbation to the wave equation introduced by a flow (e.g. Lynden-Bell & Ostriker 1967) is given by

$$\delta \mathcal{L} \xi = 2\rho_0 \partial_t v \cdot \nabla \xi.$$  \hspace{1cm} (5)

This term only captures the direct advection of waves by the flow $v$. Any associated changes in the background (non-wave) density and sound speed are neglected. The problem of the sensitivity of travel-times to changes in sound speed has already been addressed by B04. Density perturbations could be treated in essentially the same manner.

The observations used for time-distance helioseismology are typically time series of images of the line-of-sight Doppler velocity near the solar surface. For the sake of simplicity we assume that the line-of-sight is vertical. In addition, we approximate the Doppler velocity as the time derivative of the displacement at a fixed geometrical height $z_{\text{obs}} = 200$ km. In this case, the observed wavefield, $\phi(x, t)$, is related to the wave displacement by

$$\phi(x, t) = \mathcal{F} \{ \partial_t \xi_\mathcal{L} (x, t, z_{\text{obs}}) \},$$

where the function $\mathcal{F}$ denotes the action of the instrument point-spread function and any filters applied during the data analysis (e.g. phase-speed filters). In the Fourier domain, we can write the waveform as

$$\phi(k, \omega) = -i\omega F(k, \omega) \xi_\mathcal{L}(k, \omega, z_{\text{obs}}),$$

where $k$ is the horizontal wavevector, $\omega$ the angular frequency, and $F(k, \omega)$ represents the filter in the Fourier domain. Throughout this paper we will employ the Fourier convention of GB02, for a function $f$ of horizontal position and time, we have

$$f(x, t) = \int dk d\omega \ f(k, \omega) e^{i k x - i \omega t}. $$  \hspace{1cm} (8)

We will employ the same symbol for functions and their Fourier transforms, e.g. $f(k, \omega)$ denotes the transform of $f(x, t)$.

In order to compute travel-time kernels we need first to obtain Green’s functions. We define Green’s functions $G^j$ as the solutions to

$$\mathcal{L}^j G^j(x, t, z, z') = \delta_j \delta(x) \delta(t) \delta(z - z'),$$

where $\delta_j$ with $j = x, y, z$ are unit vectors along the coordinate axes. We use the same boundary conditions as in B04: zero Lagrangian pressure at the top of model S and no vertical motion at a depth of 300 Mm below the photosphere (this bottom boundary condition has essentially no effect on the computations presented here). The Green’s vector $G^j(x, t, z, z')$ gives the displacement response as a function of horizontal position $x$, time $t$, and height $z$, to a delta function source in the $\delta_j$ direction at horizontal position $0$, time $t = 0$, and height $z'$. We use the normal-mode summation approximation solution to Eq. (9) given by B04.

We now have all of the ingredients to compute travel-time kernels using the recipe of Eqs. (26) and (32) from GB02. The result for the kernels for velocity is

$$K_j(r; x_1, x_2) = 4\pi Re_{0} \int_0^\infty d\omega W^\text{diff}_j(\omega) \mathcal{C}_j(r; x_2|x_1; \omega),$$

with $j = x, y, z$. The function $W^\text{diff}_j$ is the linear sensitivity of the travel-time to changes in the cross-covariance and is defined in GB02. The sensitivity of the cross-covariance to changes in the flow $j$ is denoted by $\mathcal{C}_j^\prime$ and given by

$$\mathcal{C}_j^\prime(r; x_2|x_1; \omega) = (2\pi)^7 i^3 \omega^5 \rho_0(z) m(\omega) \times \left[ \Pi^j(x - x_1, z, \omega) \cdot \mathbf{I}(x - x_2, z, \omega) + \Pi^\dagger(x - x_2, z, \omega) \cdot \mathbf{I}^\ast(x - x_1, z, \omega) \right].$$

where $r = (x, z)$. The function $m(\omega)$ is the source auto-correlation function defined in B04. The vectors $\mathbf{I}(x)$ and $\Pi(x)$ we define in terms of their horizontal Fourier transforms

$$\mathbf{I}(k, z, \omega) = F(-k, \omega) G^j_k(-k, \omega, z_{\text{obs}}, z),$$

$$\Pi^j(x, z, \omega) = F(k, \omega) H^j_k(k, \omega, z_{\text{obs}}, z) \partial_z H^\ast_k(k, \omega, z).$$

The Green’s vector $\mathbf{H}$ is defined as

$$\mathbf{H}(k, \omega, z) = \partial_z G^j(k, \omega, z, z'),$$

where the source depth $z_{\text{src}}$ is chosen to be 100 km below the photosphere (see B04 for a discussion of the source model). The general mathematical structure of the kernels was explained by GB02.

3 Example calculations

In this section we show the results of two example calculations. The first example is for $p_1$ travel-time differences for the travel distance $\Delta = \|x_2 - x_1\| = 7$ Mm obtained using a phase-speed filter. The second example is for surface gravity wave travel-time differences at a travel distance of $\Delta = 10$ Mm.
3.1 $p_1$ ridge

For the first example, the filter function $F(k, \omega)$ is given as the product of three separate filters,

$$F(k, \omega) = F_1(k, \omega) F_2(k, \omega) \text{OTF}(k).$$

(15)

The filter $F_1$ removes the $f$-mode ridge and frequencies below 1.5 mHz and above 5 mHz. The phase-speed filter, $F_2$, is given by

$$F_2(k, \omega) = e^{-(w(k-v_p))^2/2\delta v_p^2},$$

(16)

with $k = ||k||$, $v_p = 12.8 \text{ km/s}$ and $\delta v_p = 2.6 \text{ km/s}$ (this is filter 1 from Couvidat et al. 2006). This filter isolates a section of the $p_1$ ridge. Finally a filter $\text{OTF}(k) = e^{-\alpha k}$ with $\alpha = 1.75 \text{ Mm}$ is used as a very rough approximation for the optical transfer function of the MDI/SOHO high-resolution observing mode.

Figure 1 shows slices through the components of the kernel $K$ for travel-time differences, for the $p_1$ case. Figure 1a shows a slice through $K_x$ at the photosphere. This kernel is symmetric in both $x$ and $y$. As with the kernels shown by GB02 and B04, ellipse- and hyperbola-shaped features are visible. The ringing in the horizontal directions is a result of the finite band-width of the wavefield. Figures 1b and 1c show horizontal slices through the kernels $K_y$ and $K_z$ at the photosphere. Different symmetries are visible in these slices; $K_y$ is anti-symmetric in both $x$ and $y$, while $K_z$ is symmetric in $y$ and antisymmetric in $x$. Because of these symmetries both $K_y$ and $K_z$ integrate to zero. The kernel $K_x$ has a non-zero total integral; spatially uniform flows in the $\hat{x}$ direction cause travel-time differences.

Figure 1d shows a vertical slice through $K_z$ at $y = 0$. Also shown is the ray path corresponding to a frequency of 4.5 mHz. The maximum height of the ray path is limited by the upper turning point (80 km below the photosphere). For small travel distances $\Delta$, such as the example shown here, the lower turning point of the ray path is frequency dependent. In this case we have chosen to compute a ray at 4.5 mHz, which is the frequency where the wavefield has maximum power (after filtering). The $p_1$ mode structure is visible in $K_z$. There is one maximum in sensitivity near the photosphere, and another near the lower turning point of the mode. This depth dependence will be discussed in later in this section.

A slice through $K_z$ at $y = 0$ is shown in Fig. 1e. The kernel $K_z$ is largest where the ray is mostly vertical, as expected from the ray approximation.

3.2 Surface gravity waves

For the second example we compute the sensitivity of $f$-mode travel-time differences to flow, for the case of a travel distance $\Delta = 10 \text{ Mm}$. In this case the filter function $F$ was chosen to be

$$F(k, \omega) = F_3(k, \omega) \text{OTF}(k).$$

(17)

The filter $F_3$ selects only the $f$-mode and removes all $p$-modes and frequencies below 1.5 mHz and above 5 mHz.

Figure 2 shows the results of the example $f$-mode calculation. The kernels $K_x$, $K_y$, and $K_z$ show the same symmetries as in the $p$-mode case shown in Fig. 1. As a result the kernel $K_x$ has a non-zero total integral, while $K_y$ and $K_z$ both integrate to zero.

A horizontal slice at the photosphere through $K_x$ is shown in Fig. 2a. Notice that the $K_x$ kernel is the three-dimensional version of the kernel shown by Gizon et al. (2000) and in more detail by Jackiewicz et al. (2006).

Figure 3 shows the depth dependence of the sensitivity functions shown in Figs. 1 and 2, for the case of horizontally uniform flows. In both cases, the depth dependence is roughly proportional to the kinetic energy density of the associated mode. This assumption was suggested for the $f$-mode by Gizon & Duvall (2000b).

4 Comparison with ray theory

As described in the introduction, the ray approximation (Kosovichev & Duvall 1997) has been used to predict the travel-time shifts caused by sub-surface flows. In this section we compare the predictions of the ray and Born approximations. We will consider here very simple models of flows at supergranular scales. We choose to study cylindrically symmetric flow fields, $v(r, z) = v_z(r, z) \hat{z} + v_r(r, z) \hat{r}$, of the form

$$v_y(r, z) = \alpha f(r) h(z),$$

(18)

$$v_z(r, z) = \frac{\alpha}{r} \partial_r [rf(r)] n(z),$$

(19)

where $r$ is the distance from the symmetry axis of the flow and $z$ is depth. The horizontal variation of the radial flow is given by

$$f(r) = J_0(kr) e^{-r/L},$$

(20)

where $L$ is the decay length of the flow away from the center of the cell, and $k$ is the wavenumber associated with the radial variation in the flow. The depth variation of the radial velocity we choose as

$$h(z) = e^{-(z-z_b)^2/D_2^2} - \beta e^{-(z-z_t)^2/D_2^2},$$

(21)

where $z_t$ and $z_b$ are the depths at the top and bottom of the cell, $D_1$ is the vertical scale of the outflow component of the flow, $D_2$ is the vertical scale of the inflow component, and the coefficient $\beta$ is chosen so that no vertical flows through the cell are required by mass conservation. The depth dependence, $n(z)$, of the vertical flow we then choose so that the flow satisfies mass conservation

$$\partial_z [\rho_0(z)n(z)] = \rho_0(z) h(z),$$

(22)

with the upper boundary condition $n(z) = 0$ at $z = z_t$ where $z_t$ is the top of the cellular flow.

We consider two models. Both have $(L, k) = (20 \text{ Mm}, 0.18 \text{ Mm}^{-1})$. Model A has $(z_t, z_b, D_1, D_2) = (0.2, -8, 8, 1) \text{ Mm}$ and model B has $(z_t, z_b, D_1, D_2) = (0.2, -2, 4, 0.5) \text{ Mm}$. In both cases we choose the amplitude $\alpha$ so that the maximum radial flow speed is 100 m s$^{-1}$.

Fig. 1  Slices through an example of the sensitivity of a \( p_1 \) travel-time difference to local flows. Panels (a), (b), and (c) are horizontal slices, at the photosphere, through the kernels \( K_x, K_y, \) and \( K_z \) respectively. The symmetries of these three are different. The kernel \( K_x \) is symmetric in both \( x \) and \( y \). The kernel \( K_y \) is anti-symmetric in both \( x \) and \( y \). The kernel \( K_z \) is anti-symmetric in \( x \) and symmetric in \( y \). Because of these symmetries, only \( K_x \) has a non-zero total integral, as a result the travel-time difference \( \delta \tau(x_1, x_2) \) is not sensitive (at first order) to uniform vertical flows or uniform flows in the cross-ray path direction. Panel (d) shows a slice through \( K_x \) at \( y = 0 \). The heavy black line shows the ray path. Notice that the \( p_1 \) mode structure is seen in depth. Panel (e) shows a slice through \( K_z \) at \( y = 0 \), again with the ray path shown as the heavy black line. By symmetry, the kernel \( K_y \) is zero at \( y = 0 \). In all panels the units are \( \text{s Mm}^{-3}/(\text{km/s}) \).

Fig. 2  Slices through the sensitivity of a \( f \)-mode travel time to local flows. Panels (a), (b), and (c) are horizontal slices, at the photosphere, through the kernels \( K_x, K_y, \) and \( K_z \) respectively. Panel (d) shows a slice through \( K_x \) at \( y = 0 \). Panel (e) shows a slice through \( K_z \) at \( y = 0 \). By symmetry, the kernel \( K_y \) is zero at \( y = 0 \). In all panels the units are \( \text{s Mm}^{-3}/(\text{km/s}) \).
Horizontal integrals of the \( K_x \) kernels for the \( p_1 \) and \( f \) cases (solid lines) shown in Figs. 1 and 2. Also shown are scaled kinetic energy densities (dashed lines) for the modes at the dominant wavenumber.

Model A represents a deep flow that has very little vertical variation near the photosphere. Model B represents a shallow flow. The radial and vertical flows for these two models are shown in Fig. 4.

For both models we compute the travel-time differences \( \delta \tau(x_1, x_2) \) with \( (x_1, x_2) = (x - \Delta/2, x + \Delta/2) \), where \( \Delta \) is the travel distance and \( \hat{x} \) is the unit vector in the \( x \) direction. For the ray-approximation travel times we use Eq. (15) from Kosovichev & Duvall (1997) with ray paths computed according to equation (11) of that paper, for the travel distance \( \Delta = 7 \) Mm (the same distance as for the kernels shown in Fig. 1). We compute Born approximation travel-time shifts for the \( p \)-mode case described in Sect. 3.1.

Figure 5 shows the ray and Born approximation travel-time differences for model B, the shallow flow. For this case, the ray and Born approximations give substantially different results. The main cause of this difference is that the ray approximation is not sensitive to flows that are below the lower turning point of the ray, while in the Born approximation the sensitivity extends below the lower turning point. In this particular example, the strong counter-flow is sensed in the Born approximation, but not in the ray approximation.

5 Discussion

We employed the Born approximation to obtain the three-dimensional sensitivity of time-distance measurements to advection by local flows. In this paper we addressed the important question of time-independent mass flows. We have shown that for horizontally uniform flows the depth dependence of the sensitivity of travel times is given approximately by the kinetic energy density of the mode which contributes most to the travel times.

For simple cylindrically symmetric models of supergranulation-scale convection cells we showed that the Born and ray approximations can give results that are substantially different when the flow varies in the depth range just below the lower turning point of the ray. This suggests that for inversions of supergranulation-scale flows it may be im-
important to use kernels based on the Born approximation rather than the ray approximation.

In the future, a number of improvements could be implemented: inclusion of modes above the acoustic cutoff frequency, taking spherical geometry into account, and treatment of time-dependent flows.

Acknowledgements. The work of ACB was supported by NASA contracts NNH04CC05C and NNH06CD84C. It is planned to make this kernel calculation code available through the HELAS Network.
