Niemann-Pick type C (NPC) disease is an autosomal recessive lysosomal storage disease that is caused by a mutation of the *NPC1* or *NPC2* gene, in which un-esterified cholesterol and sphingolipids accumulate mainly in the liver, spleen, and brain. Abnormal lysosomal storage leads to cell damage, neurological problems, and premature death. The time of onset and severity of symptoms of NPC disease are highly variable. The molecular mechanisms that are responsible for NPC disease pathology are far from being understood. The present study generated and characterized a zebrafish mutant that lacks Npc2 protein that may be useful for studies at the organismal, cellular, and molecular levels and both small-scale and high-throughput screens. Using CRISPR/Cas9 technology, we knocked out the zebrafish homolog of *NPC2*. Five-day-old *npc2* mutants were morphologically indistinguishable from wildtype larvae. We found that live *npc2*−/− larvae exhibited stronger Nile blue staining. The *npc2*−/− larvae exhibited low mobility and a high anxiety-related response. These behavioral changes correlated with downregulation of the *mcu* (mitochondrial calcium uniporter) gene, *ppp3ca* (calcineurin) gene, and genes that are involved in myelination (*mbp* and *mpz*). Histological analysis of adult *npc2*−/− zebrafish revealed that pathological changes in the nervous system, kidney, liver, and pancreas correlated with inflammatory responses (i.e., the upregulation of *il1*, *nfkβ*, and *mpeg*; i.e., hallmarks of NPC disease). These findings suggest that the *npc2* mutant zebrafish may be a model of NPC disease.

**Keywords**: Niemann-Pick type C, npc2, zebrafish model, Nile blue, lysosomal storage disease, neurodegeneration, inflammation, myelin

**INTRODUCTION**

Cholesterol is a lipid-type organic molecule that is critical for life. It builds, maintains, and modulates cell membranes, where it forms lipid rafts and is involved in endocytosis. It also serves as a precursor of the biosynthesis of essential biomolecules (e.g., vitamin D, sex hormones, and corticosteroids). Alterations of cholesterol metabolism were linked to arteriosclerosis in cardiovascular diseases and neurodegenerative diseases, such as Alzheimer’s disease, and Niemann-Pick type C (NPC) disease.

Niemann-Pick type C disease is a recessive lysosomal storage disease that is caused by a mutation of the intracellular cholesterol transporters *NPC1* (in 95% of cases) or *NPC2* (in 5% of cases), in...
which un-esterified cholesterol and glycolipids accumulate in lysosomes and late endosomes in the liver, spleen, and brain. The onset of the disease may vary from early childhood (most common) to adulthood, and patients present a wide range of symptoms (Vanier, 2010; Geberhiwot et al., 2018; Seker Yilmaz et al., 2020). Cholestatic jaundice and visceromegaly are often observed as the first signs of this disease. Progressive neurodegeneration is the most devastating and fatal outcome of NPC disease. Neurological symptoms of NPC disease resemble other neurodegenerative disorders, such as Alzheimer’s disease, frontotemporal dementia, and some mitochondrial disorders1.

In NPC disease, advanced hypotonia, locomotor dysfunction, ataxia, spasticity, dystonia, dysphagia, and dementia, together with developmental delay and regression, often develop in the first decade of life. These changes coincide with a lower volume of the cerebellum, hippocampus, basal ganglia, and thalamus (Geberhiwot et al., 2018). Histological analyses of mouse models of NPC disease identified the loss of Purkinje cells in the cerebellum (Sarna et al., 2003; Ko et al., 2005; Elrick et al., 2010). Aberrant myelination of the central nervous system, coinciding with a decrease in the expression of genes that are associated with oligodendrocyte differentiation (e.g., Olig1 and Olig2), has been observed in Npc1−/− mice (Yan et al., 2011; Yang et al., 2018). NPC1 disease has other hallmarks, including immune dysfunction (Baudry et al., 2003; Platt et al., 2016), early neuroinflammation, and microglia activation (Cologna et al., 2014; Kavetsky et al., 2019).

The clinical spectrum of NPC disease symptoms ranges from a rapidly progressing prenatal or neonatal form to a chronic form during adolescence. Clinical management guidelines have been developed to help physicians diagnose NPC disease (Geberhiwot et al., 2018). Cholesterol-specific Filipin staining is used as the gold standard for diagnosing NPC disease. Although very useful, this test requires culturing skin fibroblasts, which is rather demanding and cannot be performed in every laboratory. This is why Filipin staining is not recommended as a primary tool for diagnosis. In recent years, several other possible candidate stains and biomarkers have been proposed (Geberhiwot et al., 2018), but there is a need for a more robust method for NPC diagnosis that can be accomplished by genetic analyses.

Although last decade brought progress in the field of NPC, many gaps still need to be filled to improve our understanding of this disease. A further advance in understanding and managing the mechanisms that lead to neurodegeneration that is associated with NPC disease requires the use of high-throughput models, especially based on vertebrates. Zebrafish are a small tropical fish that has been used in laboratories worldwide for more than 30 years. Its significant advantages are genetic similarity to humans (over 70%), its small size, transparent body, and an externally developing body that allows in vivo observations at the cellular and organism levels from fertilization until natural death. Their rapid development, high fecundity, and relatively easy husbandry and breeding are other notable advantages. One month of fish life corresponds to approximately 2 years of human life. Most zebrafish studies that are equivalent to the age of patients can be conducted using embryos and early larval stages. The use of zebrafish as a model of human diseases also has economic value. Experiments on embryos are generally inexpensive and fast and can be readily scaled up for high-throughput screening. Zebrafish have been proven to be an excellent model for studies of lipid metabolism (Anderson et al., 2011), neuroinflammation, and neurodegenerative diseases (de Araujo Boleti et al., 2020).

A wide range of tools and techniques has been established that allow assessments of somatic and cognitive functions and developmental and pathological processes at both the cellular and organismal levels.

The human NPC1 and NPC2 genes have homologs in zebrafish. npc1 mutants were recently created (Lin et al., 2018; Tseng et al., 2018). We applied CRISPR/Cas9 technology and created a zebrafish line with a mutation of the npc2 gene (Figure 1). The homozygous npc2 mutant (npc2−/−) reflects NPC disease, which is a starting point for further studies of NPC disease. We found that Nile blue staining of the external olfactory organ can be used as a robust method for identifying npc2−/− larvae, the olfactory organ of which is affected during development.

MATERIALS AND METHODS

Animals

Zebrafish (Danio rerio), TL line, were bred and housed at the Zebrafish Core Facility (ZCF) at the International Institute of Molecular and Cell Biology in Warsaw, Poland (license no. PL14656251 from the District Veterinary Inspectorate in Warsaw; license no. 064 and 0051 from the Ministry of Science and Higher Education in Poland). All of the animal procedures were performed in accordance with fundamental ethical principles for the protection of animals that are used for scientific or educational purposes (Act of January 15, 2015; Directive 2010/63/EU). Embryos at 5–13 days postfertilization (dpf) were kept in static tanks with rotifer (Brachionus plicatilis) culture (maintained inhouse; rotifer and the rotifer diet were originally purchased from Varicon Aqua Solutions Ltd, United Kingdom). At 2 weeks of age, the fish were kept in circulating water. Fish at 13–30 dpf were fed Gemma Micro three times per day, Artemia once a day, and also received rotifers at least once a day. Thereafter, rotifers were excluded while the diet remained unchanged (dry feed three times a day and Artemia once a day). The facility maintains a 14 h light/10 h dark photoperiod. The fish were kept in groups of >5 individuals. Larvae and fish up to 6 weeks of age were kept at a maximal density of 50 fish in 3.5 L tanks. From 4 to 6 weeks of age, the fish were kept at a maximal density of 24 fish in 3.5 L tanks. Average values of water quality were the following: salinity of 800 ± 10 µS, pH 7.0 ± 0.2, temperature of 28 ± 0.4°C, undetectable NO3− and NH4+/ levels, GH 4, KH 6, dissolved O2 of 8.6 ± 0.1 mg/L, and 20% of daily water change. The chosen donor fish were outcrossed to the TL line. Some embryos were sacrificed for genotyping, and the rest were left to grow and used to establish new stable lines with a mutation of the npc2 gene.

**FIGURE 1 | Zebrafish npc2 mutant.** (A) Multiple species alignments demonstrated high conservation of the NPC2 protein among vertebrates. Arrows indicate positions of the mutation. (B) Expression levels of the npc2 gene in different tissues in adult fish. Expression was normalized to tissue with the lowest expression (brain). (C) Chromatograms confirmed a small deletion in the npc2 mutant. (D) Graphical representation of melt profiles in wildtypes (black), heterozygous mutants (blue), and homozygous mutants (gray) that originated from fish after incrossing npc2±. (E) mRNA levels of the npc2 gene in various organs in npc2−/− zebrafish relative to wildtype controls. The data are expressed as the mean ± SEM of three 9-month-old fish per group. Error bars represent the SEM. ***p < 0.001 and **p < 0.01. (F) Wildtype, heterozygous, and homozygous npc2 mutants had indistinguishable phenotypes at 5 dpf. Scale = 1 mm. (G) Morphology of adult fish. Smaller body size and weight in 8-month-old npc2−/− fish and indistinguishable phenotype of npc2±. Error bars represent the SD.

**CRISPR/Cas9**

For CRISPR prediction, the following free web tools were used to select target sites: CHOPCHOP\(^2\), E-CRISP\(^3\), CRISPRscan\(^4\), and CCTop\(^5\). Sequences that were common in at least three predictions and were scored as low risk for off-targets were chosen. The correctness of the sequence in the targeted area in the TL fish at the ZCF was confirmed by Sanger sequencing. Mutagenesis was performed according to the protocol of

\(^5\)https://crispr.cos.uni-heidelberg.de/index.html
The following gene-specific oligos with T7 overlaps were used: npc2b_5′-taatacgtcactataGTTAGACGGAAAAAGTGTGGTGTTGCTCTACAACG-3′ (to create guide IT8). During gRNA preparation, annealing and filling in steps were combined, and the template was prepared for polymerase chain reaction (PCR) using 10 μl of PCR Mix Plus (A&A Biotechnology), 2 μl of gene-specific and constant oligo (5′- AAAGCACCGACTCGGTGCTTTTCTACGTCTCTAAA CGGACTACGTCTTTATTTTAACTTGCTATTTCTAGCTCTAAA AC-3′; each at 100 mM stock), 2 μl dNTPs (100 mM stock), and water up to 20 μl. The PCR conditions were the following: pre-incubation at 95°C for 3 min, followed by 35 cycles of 95°C for 15 s, 40°C for 15 s, and 68°C for 15 s. sgRNA was prepared using 1 μl of gene-cleaned template (145 ng), 0.5 μl T7 RNA polymerase (20 U/μl, A&A Biotechnology), 2 μl dNTPs (75 mM each, A&A Biotechnology), 1 μl of buffer (5×, A&A Biotechnology), and water up to 5 μl. The reaction was incubated for 2 h at 37°C. Thereafter, a mixture of 1 μl of RNA-free DNAse (Qiagen) and 14 μl of water was added to each sample. After 15 min of incubation, 10 μl of ammonium acetate (5 M stock) and 60 μl of pure ethanol were added, and the samples were left for precipitation overnight at -20°C. gRNA was suspended in water, and the concentration was adjusted to 500 ng/μl. Cas9 protein (14 mg/ml stock, made in-house) was diluted in KCl/HEPES (200 mM/10 mM, pH 7.5) buffer to a final concentration of 600 ng/μl. The reaction mixture was assembled fresh by mixing 2 μl of gRNA, 2 μl of gRNA, and 0.4 μl phenol red (Sigma, catalog no. P0290) and left for complex formation at room temperature for 5–10 min. Thereafter, the samples were kept on ice.

**Injections**

Microneedles were pulled from borosilicate glass capillaries (Sutter; catalog no. BF 100-50-10) using a P-1000 Flaming/Brown micropipette puller (Sutter) set to the following parameters: n = 4 wildtypes). Additionally, to test the influence of 2-hydroxypropyl-β-cyclodextrin (2HPβCD) treatment (a drug that is used for the treatment of Niemann-Pick disease) on the expression of selected genes, total RNA was extracted from two groups of treated and untreated zebrafish larvae (5 dpf) from two independent experiments. The RNA template (1,000 ng) was used for cDNA synthesis using the iScript cDNA Synthesis Kit (Bio-Rad).

**DNA Extraction**

Fin clipping of adult zebrafish was performed under anesthesia with tricaine (Sigma, catalog no. A-5040). The fish were immersed in 0.7 mM tricaine solution in system water until they stop moving and exhibited no response to touch. Euthanasia of - larvae was performed by an overdose of tricaine. Fish tissue (fragment of the tail fin or pulls of 3–5 dpf embryos) was dehydrated in pure ethanol, incubated at 80°C until complete dryness, soaked in 50–150 μl of TE 10-1 buffer [aqueous solution of 10 mM Tris (pH 8.0) and 1 mM ethylenediaminetetraacetic acid (pH 8.0)] and cooked for 10 min at 95°C. Thereafter, an equal volume of TE 10-1 with 20–60 μg proteinase K (10 mg/ml aqueous stock) was added to each sample. The samples were incubated for 1 h at 55°C. Proteinase K was then inactivated by heat (incubation for 15 min at 95°C). Samples were stored at −20°C before use.

**DNA Sequencing**

For sequencing, the amplicon was amplified with PCR Mix Plus (catalog no. 2005–100P, A&A Biotechnology) and npc2_a_F1 5′-GCATATCGCTGTACGTGATT-3′ and npc2_b_R1 5′-GTAGGATTGTCCCTGGTAAGC-3′ primers. The PCR conditions were preincubation at 95°C for 3 min and 35 amplification cycles of 95°C for 15 s, 60°C for 15 s, and 72°C for 15 s, followed by 5 min of incubation at 72°C. The PCR products were purified using EPPIC Fast (catalog no. 1021–100F, A&A Biotechnology) according to the manufacture’s protocol.

**RNA Isolation and cDNA Synthesis**

The fish were anesthetized with an overdose of tricaine. RNA was isolated using TRI reagent (Sigma, catalog no. T9424) according to the manufacture’s instructions. The tissue was shredded in 1 ml of solution with a 23-gauge needle. After the addition of 0.2 ml of chloroform, the sample was vortexed and centrifuged at 13,000 rotations per minute (rpm) for 15 min in 4°C. The supernatant was transferred to a new tube, and RNA was precipitated with pure isopropanol overnight at −20°C. After centrifugation at 13,000 rpm for 30 min at 4°C, the pellet was washed with 70% ethanol, air-dried, and resuspended in 15–25 μl of sterile water. Total RNA was extracted from 5 dpf larvae (n = 9/group from at least two independent cohorts), and various organs (brain, liver, heart, spleen, skeletal muscles, and gonads) were collected from 9-month-old male fish (n = 4 homozygotes and n = 4 wildtypes). Additionally, to test the influence of 2-hydroxypropyl-β-cyclodextrin (2HPβCD) treatment (a drug that is used for the treatment of Niemann-Pick disease) on the expression of selected genes, total RNA was extracted from two groups of treated and untreated zebrafish larvae (5 dpf) from two independent experiments. The RNA template (1,000 ng) was used for cDNA synthesis using the iScript cDNA Synthesis Kit (Bio-Rad).

**High-Resolution Melting (HRM) Analysis**

The reaction mixture was composed of (i) 5 μl of LightCycler 480 High Resolution Melting Master mix (Roche), 1 μl of MgCl2 (25 mM stock), 0.3 μl of each primer (10 μM stock), 0.5 μl of template, and water up to 10 μl or (ii) 5 μl of Precision Melt Supermix (Bio-Rad), 0.2 μl of each primer (10 μM stock), 1.0 μl of template, and water up to 10 μl. Two primer pairs were used, npc2a HRM F1 (5′-AACTCTAGTTGTAGTGTTCCCTAAC-3′) and npc2a HRM R1 (5′-CAAGTGTACGCCAGAAAGAGTA-3′) were used as controls, which amplified the region upstream of the target site. npc2b HRM F1 (5′-TAATTCCACTTCTCATCTTACGCGC-3′),npc2b HRM F1 (5′-TAATTCCACTTCTCATCTTACGCGC-3′),
and npc2b HRM R1 (5’-GGATTGTCCCTTGTGAAGCTTG-3’), which span the mutation site, were used to detect the mutation. HRM analysis was performed on either LightCycler 480 System PCR (Roche) or CFX96 (Bio-Rad), both according to the manufacturer’s protocol. For the Bio-Rad system, the conditions were preincubation at 95°C for 2 min, 35 amplification cycles of 95°C for 10 s and 60°C for 30 s, heteroduplex formation at 95°C for 30 s, followed by 60°C for 1 min, and HRM at 65–95°C with ramp at 0.2°C/10 s. Genotypes were automatically assigned by LightCycler 96 software’s HRM module for the Roche system or Precision Melt Analysis software for the Bio-Rad system and manually annotated as wildtype (black), heterozygous mutant (blue), and homozygous mutant (gray; Figure 1).

Quantitative PCR Gene Expression Analysis

Gene expression levels were analyzed using the CFX Connect Real-time PCR (RT-PCR) Detection System (Bio-Rad, Hercules, CA, United States). RT-PCR was performed in duplicate using SsoAdvanced Universal SYBR Green Supermix (Bio-Rad, catalog no. 1725274). The data were analyzed using Bio-Rad CFX Maestro 1.0 software. The specificity of the reactions was determined based on dissociation curve analysis. Fold changes were calculated using the ΔΔCq method as described before (Majewski et al., 2019). Expression levels were compared between groups using analysis of variance (ANOVA) followed by Tukey’s Honestly Significant Difference (HSD) post hoc test. The 18S ribosomal gene was used as a reference. The sets of primers that were used in the analysis are shown in Table 1.

LysoTracker, Filipin, Neutral Red and Nile Blue Staining

Nile blue (B&K, Bytom, Poland) was prepared as a 1% aqueous stock solution. Stock solution of neutral red (Sigma N7005) was prepared as 2.5 mg/ml solution in water. LysoTracker Red DND-99 (Invitrogen, catalog no. L7528), Neutral red or Nile blue (each at 1:1000 dilution) was added directly into the plates with live 5-day-old zebrafish larvae. After 1 h of incubation at 28°C in the dark, the medium was exchanged to fresh E3 three times over a 15 min period.

The stock of filipin complex (Sigma, catalog no. F9765) was prepared by dissolving 25 mg filipin in 1 ml of dimethylsulfoxide. Aliquots of stocks were stored at −20°C. 5-day-old zebrafish larvae were fixed in 4% paraformaldehyde (Sigma, catalog no. 47608) in 1 x phosphate-buffered saline (PBS; Sigma, catalog no. D5652) for 1 h at room temperature and washed for 5 min three times with 1 x PBS with 1.5% glycine (Sigma, catalog no. G7126). Embryos were stained with filipin solution (final Filipin concentration of 0.5 mg/ml) in 1 x PBS with 10% bovine calf serum (Sigma, catalog no. 12133C) in the dark for 2 h at room temperature.

Stained larvae were rinsed with 1 x PBS, immersed in 0.7 mM tricaine, transferred to a plate with 3% methylcellulose, and imaged in the ultraviolet channel (Filipin), RFP channel (LysoTracker), and bright field (Nile blue) under a Nikon SMZ25 fluorescent stereomicroscope. The genotype of the imaged fish was confirmed by HRM analysis.

Treatments

The stock solutions were prepared by dissolving the powdered compound in Milli-Q water to a final concentration of 100 mM for (2-hydroxypropyl)-β-cyclodextrin (2HPβCD; Sigma, catalog no. C0926) and 10 mM for 3-β-[2-(diethylamino)ethoxy]androst-5-en-17-one (U18666A; Sigma, catalog no. 662015). Good-quality eggs were placed in 9 cm diameter Petri dishes filled with 25 ml of E3 medium and kept under static condition at 28 ± 0.5°C. At 3 dpf, the medium was changed to fresh E3 medium supplemented with U18666A (8 μM), 2HPβCD (2 mM), and U18666A (8 μM) together with 2HPβCD (2 mM). As a control, an equal volume of the solvent was used. Embryos were kept in static condition for 2 days. At 5 dpf, the fish were stained with Nile blue and collected for RNA extraction.

Histology

Adult zebrafish were fixed in neutral buffered 4% formaldehyde solution (Sigma, catalog no. 47608–250ML-F), dehydrated in ethylene, and embedded in paraffin. Longitudinal and transverse 5–6 μm sections were cut using a Leica microtome (RM2265, Leica, Bensheim, Germany) and stained with standard hematoxylin and eosin (H&E). For glycogen and lipofuscin inclusions, periodic acid-Schiff (PAS) reactions were performed according to the manufacturer’s instructions (Sigma-Aldrich, St. Louis, MO, United States). Perl Prussian blue staining to detect hemosiderin was performed according to Orchard (2019). Luxol Fast Blue (LFB), combined with H&E, was used to stain myelin sheaths. The immunohistochemical frequency of CD3 and proliferating cells in the intestinal epithelium and liver was determined in samples that were stained according to the manufacture’s protocol for anti-CD3 (Bond Ready-to-Use Primary Antibody CD3, LN10, Leica, Newcastle, United Kingdom) and anti-proliferating cell nuclear antigen (PCNA; 1:400 dilution; clone PC10, DAKO, Poland) antibodies. The colorimetric detection of these cells was performed using DAB (Novolink Polymer Detection Kit, Novocastra, Leica, Newcastle, United Kingdom). The microscopic analysis was performed using NIS Elements software and Nikon Ni-E with NIS Elements software.

Behavioral Analysis

The behavioral studies of zebrafish larvae were performed as described previously (Wasilewska et al., 2020). Before the experiment, the larvae were kept in a Petri dish (~50 larvae/dish) that was two-thirds filled with E3 medium in an HPP110 incubator (Memmert) that was set to 28.5°C under a 14 h/10 h light/dark cycle with 20% light intensity (cold/warm light, 1:1) and 60% humidity. The larvae (5 dpf) were transferred to 12-well plates and placed in a ZebraBox high-throughput monitoring system (ViewPoint Life Sciences, Lyon, France). The experiments were performed in a volume of 2 ml of E3 medium, and the light intensity was set to 70%. Locomotor activity was recorded for 15 min using ZebraBox. A total of 40 wildtype...
Tukey’s HSD post hoc test. In the behavioral studies the Wilcoxon rank-sum test was used for comparisons between wildtype and npc2<sup>−/−</sup> larvae.

**RESULTS**

**Generation and Phenotype of the npc2 Zebrafish Mutant**

The zebrafish npc2 gene (ENSDARG00000090912) maps to chromosome 17 and encodes a 149 amino acid protein that shares over 64% sequence identity with its human ortholog (Figure 1A). Expression of the npc2 gene could be found in each tested tissue (i.e., brain, heart, liver, muscles, skin, and reproductive organs; Figure 1B). Using CRISPR/Cas9 technology and gRNAs that targeted the npc2 gene, we generated F0 carriers of different mutations. After an initial screening by HRM analysis, six donor fish with the most distinct HRM patterns were bred, and their F2 offspring were analyzed by HRM and sequencing. A mutant line with a 1 bp deletion in the third exon of the npc2 gene (ENSDARG00000090912) that is predicted to introduce a premature stop codon was selected for further studies (Figure 1C). The deletion caused a characteristic shift in the melting temperature of the amplicon that was identified by HRM (Figure 1D). In the mutant, qPCR analysis confirmed a significantly lower level of npc2 transcripts (Figure 1E). At 5 dpf, the morphology and length of the hetero-

**Statistical Analysis**

In quantitative PCR gene expression analysis, expression levels were compared between groups using ANOVA followed by
and homozygous \(npc2\) mutants were indistinguishable from wildtype siblings (Figure 1F), similar to \(npc1\) zebrafish knockouts (Lin et al., 2018; Tseng et al., 2018). Over time, the differences became more apparent. The 2-month-old \(npc2^{-/-}\) fish were smaller than their siblings, and the sex ratio of homozygotes was skewed toward males (data not shown). When separated from their siblings, the \(npc2^{-/-}\) fish did not need to compete for food and grew faster. From 4 months of age, their motor functions were clearly impaired (Supplementary Video 1) as compared to wildtype siblings (Supplementary Video 2). The malnutrition and progressive loss of motor skills continued to worsen, but not all \(npc2^{-/-}\) fish were equally affected. Some fish had to be euthanized at the age of 5 months because their eating and swimming skills were severely impaired, whereas others were fit and survived four more months. The length and weight of the 9-month-old \(npc2^{-/-}\) fish were significantly reduced (Figure 1G). The \(npc2^{-/-}\) fish bred normally, whereas inbreeding of the \(npc2^{-/-}\) fish was unsuccessful (data not shown). Interestingly, we could obtain offspring by crossing \(npc2^{-/-}\) males with either wildtype or \(npc2^{+}\) females.

Nile Blue Staining Identifies \(npc2^{-/-}\) Larvae

Although, nowadays not recommended as a primary tool, the cholesterol-specific filipin staining for many years was used as a gold standard in NPC diagnostics (Geberhiwot et al., 2018). That is why we applied this stain to the mutant fish and confirmed the presence of blighter signals in the \(npc2^{-/-}\) mutant (Supplementary Figure 1). This finding indicates that as expected, un-esterified cholesterol accumulates in homozygous \(npc2\) mutant.

Niemann-Pick type C disease is a lysosomal storage disease. We used the LysoTracker red probe to visualize acidic organelles in vivo to quickly identify the mutant. We observed increased in LysoTracker red staining in neurromasts in some \(npc2^{-/-}\) larvae (Supplementary Figure 2). However, using this staining, we failed to reliably distinguish wildtype from \(npc2^{-/-}\).

We found that Nile blue staining allowed the robust and reliable detection of \(npc2^{-/-}\) larvae. When added to the water in the dish, Nile blue reversibly stained live larvae in a few minutes. At 5 dpf, strong staining in the peripheral olfactory organ was specific (certainty > 95%) to \(npc2^{-/-}\) fish, whereas staining in other parts of the body appeared random (Figure 2).

Nile blue stains lipids. It has been primarily used to detect melanin and lipofuscin (Lillie, 1958). Nile blue-based dyes were later discovered to localize in lysosomes. Their lysosomotropic photosensitizer properties could be used to target and kill tumor cells (Gattuso et al., 2016; Martinez and Henary, 2016). To photosensitizer properties could be used to target and kill tumor

Decrease in Locomotor Activity in \(npc2^{-/-}\) Zebrafish Larvae

To investigate the effect of \(npc2\) mutant on behavior, locomotor activity in \(npc2^{+/+}\) and \(npc2^{-/-}\) zebrafish larvae was analyzed. A significant reduction of mobility was observed in \(npc2^{-/-}\) larvae compared with their wildtype siblings (Figure 4A). Mutants traveled a shorter distance (Figure 4B), and they remained mobile for a shorter period of time (Figure 4C). The mean velocity during the first 5 min of the experiment was lower in \(npc2^{-/-}\) larvae compared with \(npc2^{+/+}\) larvae (Figure 4D). During the initial 5 min of the experiment, mutant larvae exhibited a stronger tendency to stay in close proximity to the borders of the well (thigmotaxis, Figure 4E). This phenomenon is a typical anxiety-like response in zebrafish larvae (Lundegaard et al., 2015), suggesting a stronger anxiety-related response to a stressor in this group.

Pathological Changes in Internal Organs in Adult \(npc2^{-/-}\) Fish

The histopathological analysis of adult \(npc2^{-/-}\) larvae revealed lesions in the spleen, liver, and pancreas. In the liver in \(npc2^{-/-}\) fish, numerous foam hepatocytes, hepatocytes that contained fat droplets, and cells with enlarged nuclei were observed (Figure 5A). An atypical interstitial group of foam cells was observed in the anterior part of the \(npc2^{-/-}\) kidney (Figure 5B). The structure of the pancreas was disturbed. Acinar cells in the pancreas in \(npc2^{-/-}\) larvae had no characteristic zymogen granules but had multiple circular cholesterol inclusions that were not observed in the control group (Figure 5C).

Morphological and histopathological changes were also observed in the brain in \(npc2^{-/-}\) fish (Supplementary Figure 3 and Figure 6). The myelination of axons in \(npc2^{-/-}\) fish was affected (Figure 6A), especially in the habenular commissure (Figures 6B,C). The habenula's characteristic layered structure was affected. The fascicular retroflexus, interpeduncular nucleus, and raphe were vacuolated, and the myelination of axonal tracts decreased (Figures 6B,C). The two mecanoreceptive areas with well-differentiated axonal tracts (lateral and medial longitudinal fascicle) were observed only in wildtype fish compared with \(npc2^{-/-}\) fish (Figure 6C). In the cerebellum, Purkinje cells were more diffuse than in the control group, and the structure on these cells differed from control fish (Figures 6C, 7A). Purkinje cells had spheroid, highly non-condensed chromatin, enlarged nuclei, and a distended perikaryon (Figure 7A). In this region, no PCNA-positive cells were observed, although proliferation was detected in the parvocellular preoptic nucleus and caudal zone of the periventricular hypothalamus compared with the control group (Supplementary Figure 4A).

In the olfactory sensory epithelium, no histopathological changes were observed, although the olfactory nerve had some degenerative attributes, characterized by a shrunken cytoplasm of axons that were visible in transversal sections. Similar histopathological changes were observed in the telencephalon.
FIGURE 2 | Nile blue staining distinguishes \textit{npc2}^{-/-} fish from wildtype and heterozygous siblings. The strong signal could be detected in the peripheral olfactory organ in 5-day-old \textit{npc2}^{-/-} larvae (B–B”) unlike their siblings (A–A”). (A,B) lateral view; (A’,A”,B’,B”) dorsal view; and (A”,B”) enlarged fragments of A’,B”. respectively. Arrows indicate the position of the olfactory organ. Scale bar = 0.5 mm.

FIGURE 3 | Specificity of Nile blue staining in the olfactory organ in \textit{npc2}^{-/-} larvae at 5 dpf. (A–A”) untreated \textit{npc2}^{-/-} larvae; (B–B”) treatment with 2 mM 2-hydroxypropyl-\beta-cyclodextrin (2HP\betaCD; a drug that is used in clinical trials to treat NPC patients) decreased staining intensity to wildtype levels (Figures 2A–A”); and (C–C”) treatment with 8 mM (3β-[diethylamino]ethoxy)androstan-5-en-17-one hydrochloride (U18666A, an inhibitor of cholesterol synthesis that is used to model NPC chemically) increased staining intensity in \textit{npc2}^{-/-} larvae. (A–C) lateral view; (A’,A”,B’,B”,C’,C”) dorsal view; and (A”,B”,C”) enlarged fragments of A’,B’,C”. respectively. Scale bar = 0.5 mm.
and rhombencephalon (Figure 6A). In the external and internal cellular layers of the olfactory bulb, multiple vacuolations were observed in intracellular matter, but no neural cytopathological changes were found. Widespread foamy vacuolation of the cytoplasm of neurons and glia and neuronal spheroids were present in the npc2−/− telencephalon and optic tectum (mostly in the stratum fibrogriculare). Similar changes were observed in the olfactory bulb and optic nerve (Figures 7B, C). CD3-positive cells were observed in npc2−/− fish, whereas no signal was detected in the wildtype group (Supplementary Figure 4B).

We determined the level of gene expression in wildtype and npc2−/− fish at two developmental stages. Homozygous larvae were preselected based on Nile blue staining. The genotype of both 5-day-old larvae and adult fish was confirmed by HRM analysis. In whole larvae, the mbp, cldn, and olig1 genes were down-regulated, whereas expression of the mpz, plp1, and sox10 genes was unchanged. In the npc2−/− adult brain, a significant reduction of expression was detected only for the mbp and mpz genes (Figure 8). The downregulation of myelination markers was consistent with the decrease in LFB staining (Figure 6A).

Alterations of Expression of Genes That Shape Inflammation, Autophagy and Ca²⁺ Signaling in npc2−/− Fish

The downregulation of mbp expression is associated with the upregulation of interleukin-1 signaling in npc1−/− animal models (Mannie et al., 1987; Qiao et al., 2018). To determine whether npc2−/− zebrafish exhibit hallmarks of inflammatory responses that are associated with NPC disease, we profiled the expression of selected genes in the brain and liver in 9-month-old fish. In the brain, the upregulation of il1, nfκβ, mpeg, and capn2a was detected (Figure 9). In the liver, il1 expression but not nfκβ, mpeg, or capn2a expression was also up-regulated. However, in...
FIGURE 5 | Pathological changes in soft tissues in npc2−/− revealed by H&E staining. (A) Cells with enlarged nuclei (black arrow), hepatosteatosis with different type of fatty droplet accumulation (open arrowhead) and foam cytoplasm (asterix) were found in npc2-deficient livers. (B) Kidneys with degenerating cells (DMc) between ductal (DT) and proximal (PT) tubules. (C) Pancreas with degeneration of zymogen granules in acinar cells and cholesterol deposits. The paraffin sections are from adult npc2−/− fish and wildtype npc2+/+ control. Scale bar = 50 µm.

contrast to the brain, mpx, apoE, and ppp3ca expression was up-regulated (Figure 9).

In addition, we stained zebrafish larvae with Neutral red, a dye which specifically labels microglia in the larval zebrafish brain. In 5 dpf npc2−/− larvae, we found numerous red-labeled cells with dark red aggregates having typical appearance of over-activated micro-microglia, i.e., soma size was enlarged and cells had amoeboid shape (Supplementary Figure 5). Beclin-1 plays an important role autophagy during neurodegeneration. We found that npc2−/− larvae show slightly increased expression level of becn1, which is in line with previous finding of Pacheco and colleagues who demonstrated that enhanced basal autophagy in NPC1 deficiency is mediated by increased expression of Beclin-1 (Pacheco et al., 2007). We did not detect significant changes in the expression level of markers of ubiquitin-dependent stress-induced autophagy (atg5, atg7, and p62; Supplementary Figure 6).

We also found that apoE, capn2a, lgals3a, mcu, mpeg, and ppp3ca expression were down-regulated in 5 dpf npc2−/− larvae compared with wildtype fish (Figure 10A). The most striking difference was related to the level of mcu, with very high statistical significance. These changes appeared to be specific to NPC disease because 2HPβCD treatment rescued the levels of mcu and ppp3ca expression and the expression of genes that are associated with myelination (olig1, mbp, cldn, and plp1; Figures 8, 10B).
FIGURE 6 | Pathological changes in the central nervous system in adult npc2−/− zebrafish. (A) Luxol fast blue staining showed differences in myelination between wildtype and npc2−/− fish. (B) Changes in habenula structure were present in some npc2−/− fish, which lacked the characteristic structure of this part of the habenular tract. (C) Midbrain with vacuolization of the habenula tract (blue arrow) with fascicular retroflexus (blue arrowhead) and degenerative changes in the medial and lateral longitudinal fascicle. OB, olfactory bulb; OR, olfactory rosette; Te, telencephalon; TeO, tectum opticum; Ce, cerebellum; Me, medulla; PG, preglomerular complex; and PT, posterior tuberculum. (A) LFB staining. Scale bar = 500 µm. (B, C) H&E staining. Scale bar = 100 µm. (C) scale bar = 500 µm.
FIGURE 7 | Pathological changes in npc2<sup>−/−</sup> sensory organs. (A) Cerebellum structure with Purkinje cells degeneration in npc2 mutant (gray arrow), (B) Olfactory rosette with olfactory nerves (white arrow), (C) Optic nerve ganglion. Cells with a foamy, pale cytoplasm, eosinophilic nuclei, and signs of degeneration (black arrows) within the optic tectum. (A) ML, molecular layer; P, Purkinje cell layer; GL, granule cell layer; OfN, olfactory nerves; and OR, olfactory rosette; (B) OT, optic tectum; OpG, optic nerve ganglion. H&E staining. Scale bar = 50 µm.

FIGURE 8 | Decrease in myelination in npc2-deficient larvae and adult fish. Scatter plots show the normalized expression of selected genes in 5 dpf larvae and in the brain in npc<sup>−/−</sup> and wildtype zebrafish. Each circle corresponds to one zebrafish. The 18S ribosomal gene was used as a reference. At least three samples were analyzed. **p < 0.001; *p < 0.01; and *p < 0.05.
DISCUSSION

Niemann-Pick type C disease is a rare disease. The elucidation of its pathogenesis can help understand the molecular mechanisms that underlie more common disorders that are related to impairments in cholesterol homeostasis, autophagy, inflammation, and neurodegeneration. Accumulating evidence links cholesterol transport inhibition with lower susceptibility to viral infection, including SARS-CoV-2 (Gong et al., 2016; Wec et al., 2016; Stoeck et al., 2018; Ballout et al., 2020; Sturley et al., 2020; Vial et al., 2020), and studies of NPC genes are highly relevant. Of two human NPC genes, NPC1 and its homologs have been the most studied (Fog and Kirkegaard, 2019; Wheeler and Sillence, 2020). Various tools have been created and successfully applied to advance our knowledge of NPC1 function in normal and pathological processes (Lin et al., 2018; Tseng et al., 2018; Fog and Kirkegaard, 2019). Surprisingly, little is known about NPC2, a soluble lysosomal protein that delivers cholesterol to NPC1 (Deffieu and Pfeffer, 2011). Homologs of both the human NPC1 and NPC2 genes are conserved in zebrafish. Zebrafish ncp1 mutants were recently described (Lin et al., 2018; Tseng et al., 2018). To our knowledge, no zebrafish mutant is available for ncp2. To fill this gap in the literature, we created and characterized homozygous ncp2−/− fish. Clinical manifestations in humans who are deficient in NPC1 or NPC2 are similar. Hence, unsurprising is that ncp2−/− zebrafish in many ways resemble the phenotype of ncp1−/− fish. In the present study, we found that the manifestation of the ncp2 mutation resembles changes that are seen in human patients. NPC disease can be highly heterogeneous in patients (Vanier, 2010; Reunert et al., 2016). In ncp2 mutant fish, we observed variability in symptoms and their intensity. Similar to patients, ncp2−/− fish exhibited clear signs of neuropathy and cytological changes in the liver and pancreas. Fish do not have bone marrow, and hematopoietic processes are conducted by the thymus, spleen, and anterior kidney. These three major hematopoietic organs were affected, and cells with a characteristic foam cytoplasm were observed, similar to several human diseases (Eom et al., 2015) and animal models (Kuemmel et al., 1997) of renal degeneration. Foam cells within the ncp2−/− brain were also present in NPC patients and mouse models. Defects in Purkinje cells in the cerebellum were found in adult ncp2−/− fish. In addition to histological changes, ncp2−/− fish also recapitulated molecular changes, including alterations of the expression of genes that are involved in myelination and inflammation. However, gene expression was not changed in the same manner in larvae and adults. This is unsurprising because adult fish were severely affected, whereas the disease just started to progress in 5-day-old larvae.

Links between mitochondria, lysosomes, and neurodegeneration have been confirmed previously (Saffari et al., 2017; Torres et al., 2017). Mitochondrial dysfunctions have also been described in human cells with a mutation in the human NPC1 gene and in corresponding mouse models (Woś et al., 2016; Erickson et al., 2020). We found a significant decrease in expression of the mcu gene in ncp2−/− larvae. 2HPβCD treatment rescued expression levels. To our knowledge, this is the first study that found that impairments in calcium uptake into mitochondria may contribute to NPC disease. We previously reported that mcu knockout can rescue pink1 mutant zebrafish, a model of Parkinson’s disease, from the loss of dopaminergic neurons (Soman et al., 2019). Alterations of calcium homeostasis and signaling are not restricted to mitochondria. NPC disease was linked to a decrease in the expression of Ppp3ca in the mouse
and weight compared with wildtype and heterozygous siblings. Tseng et al. suggested that “the growth defect observed in the npc1 mutant zebrafish may be due to impaired feeding” (Tseng et al., 2018). Lawrence et al. reported that the sex ratio in zebrafish is strongly influenced by the feeding regimen, and fish that eat more are more likely to become female (Lawrence et al., 2008). npc2<sup>−/−</sup> fish and their heterozygous and wildtype siblings occupied the same tank. The sex ratio is skewed in npc2 mutants, and npc2<sup>−/−</sup> fish tend to be males, whereas their wildtype siblings tend to be mostly females. Thus, growth restriction and male-rich population of npc2<sup>−/−</sup> fish may be at least partially attributable to an inability to take food. Moreover, anatomical and histological changes in the olfactory and optic neuron tracts and degenerative changes in mechanosensory fibers may hinder the ability of npc2<sup>−/−</sup> fish to find food.

Despite the smaller body size, adult npc2<sup>−/−</sup> fish produced gametes, but our attempts to inbreed these fish were unsuccessful. A similar problem was reported for Npc2<sup>−/−</sup> mice (Busso et al., 2010, 2014) and Npc1<sup>−/−</sup> zebrafish (Tseng et al., 2018). However, we found that male npc2<sup>−/−</sup> fish could occasionally mate with npc2<sup>−/−</sup> female fish, resulting in viable offspring. This finding is consistent with the observation by Busso et al. (2014) that male Npc2<sup>−/−</sup> mice generated sperm that could fertilize eggs in vitro, although they did not mate. These authors suggested that locomotor dysfunction prevents male fish from breeding, but other factors might contribute to this problem. Abnormal cerebellar morphogenesis could be one of the factors (Caporali et al., 2016). Mating behavior involves social integrations, in which odor communication plays an important role. Impairments in the sense of smell is an early marker of neurodegenerative diseases. We found pathological changes in the olfactory system in npc2<sup>−/−</sup> fish. Sensory deficits that are associated with pronounced neurodegeneration in the olfactory system have also been described in Npc1<sup>−/−</sup> mice (Hovakimyan et al., 2013). Therefore, tremor, defective movements, and an inability to respond to chemical cues likely prevented animals with NPC disease from successfully breeding.

Niemann-Pick type C disease patients often exhibit neuropsychiatric symptoms (Evans and Hendriksz, 2017; Mengel et al., 2017; Patterson et al., 2017). In behavioral tests, npc2<sup>−/−</sup> larvae exhibited a range of behavioral changes, including an increase in anxiety-like behavior upon stress exposure. Studies showing decreased exploratory activity, hyperactivity and reduced anxiety were performed on mice, but only on adult animals which motor skills already were impaired and hence their performance may have been affected (Voikar et al., 2002; Gómez-Grau et al., 2017). Similar to fish, behavioral changes can be quantified in 5-day-old tremor-free animals, and disease progression can be followed over time. The test may be scalable. The zebrafish model of NPC disease presents unique features that may help efficiently and reliably detect early changes, monitor disease progression, and assay drug efficiency.

Although several NPC models exist, many gaps still need to be filled to improve our understanding of this disease. The npc2 mutant makes an important contribution to the range of existing models that allow further studies of NPC disease and other neurodegenerative cholesterol-dependent disorders.

![FIGURE 10](image-url)
at the organismal, cellular, and molecular levels. Experiments in zebrafish are scalable and suited for high-throughput drug screens. The zebrafish npc2 mutant may be utilized as a helpful model for the drug development pipeline in early stages of NPC disease. Another issue is the clinical diagnostic value of Nile blue, a dye that specifically provides a strong stain in the nose in npc2−/− larvae.

DATA AVAILABILITY STATEMENT

The raw data supporting the conclusions of this article will be made available by the authors, without undue reservation.

ETHICS STATEMENT

All activities were performed in compliance with fundamental ethical principles (Protection of animals used for scientific or educational purposes, Act of January 15, 2015; Directive 2010/63/EU). The majority of the experiments were performed in 5-day-old zebrafish larvae (a stage at which zebrafish are not considered protected animals). The experiments did not qualify as a subject of review by the local ethical committee. In the case of adult fish, recording their natural behavior was performed without any interference. The fish remained in their home tank, and no handling or any other intervention that could cause any pain or distress was applied to them. Consequently, this action did not classify as a procedure and did not require any permit from the ethics committee.

AUTHOR CONTRIBUTIONS

MW, LM, IW, and JK conceived and planned the experiments. MW, LM, IW, and DA-U performed the experiments. MW, LM, IW, and JK contributed to interpretation of the results. MW took the lead in writing the manuscript. All authors provided critical feedback and helped shape the research, analysis, and manuscript.
