Abstract

We perform a Very Large Telescope FOcal Reducer and low-dispersion Spectrograph 2 narrowband imaging search around five star-forming galaxies at redshift $z = 0.67–0.69$ in the Great Observatories Origins Deep Survey South field to constrain the radial extent of large-scale outflows traced by resonantly scattered Mg II emission. The sample galaxies span star formation rates in the range $4 \ M_\odot \ yr^{-1} < SFR < 40 \ M_\odot \ yr^{-1}$ and have stellar masses $9.9 < \log M_*/M_\odot < 11.0$, and exhibit outflows traced by Mg II absorption with velocities $\sim 150–420 \ km \ s^{-1}$. These observations are uniquely sensitive, reaching surface brightness limits of $5.81 \times 10^{-19} \ erg \ s^{-1} \ cm^{-2} \ arcsec^{-2}$ per 1 arcsec$^2$ aperture (at $3\sigma$ significance). We do not detect any extended emission around any of the sample galaxies, thus placing $<5\sigma$ upper limits on the brightness of extended Mg II emission of $<6.51 \times 10^{-19} \ erg \ s^{-1} \ cm^{-2} \ arcsec^{-2}$ at projected distances $R_\perp > 8–21 \ kpc$. The imaging also resolves the Mg II absorption observed toward each galaxy spatially, revealing approximately constant absorption strengths across the galaxy disks. In concert with radiative transfer models predicting the surface brightness of Mg II emission for a variety of simple wind morphologies, our detection limits suggest that either (1) the extent of the Mg II-emitting material in the outflows from these galaxies is limited to $<20 \ kpc$; or (2) the outflows are anisotropic and/or dusty.

Key words: galaxies: evolution – galaxies: halos

1. Introduction

Galactic winds likely play a critical role in regulating the star formation rates (SFRs) and stellar masses of galaxies (e.g., Somerville & Primack 1999; Kereš et al. 2009; Oppenheimer et al. 2010; Hopkins et al. 2014; Werk et al. 2014); however, the physics that powers these winds remains uncertain. Some possible mechanisms have been proposed by theoretical studies that include thermal pressure from core-collapse supernovae, radiation pressure from starbursts, and cosmic ray pressure (e.g., Larson 1974; McKee & Ostriker 1977; Chevalier & Clegg 1985; Breitschwerdt et al. 1991; Springel & Hernquist 2003; Murray et al. 2011; Uhlig et al. 2012). Additionally, the impact galactic winds have on their host galaxies (i.e., their mass and energy content) has remained difficult to constrain with observations.

An accurate picture of the types of galaxies that host outflows comes from numerous absorption line studies of galaxy spectroscopy (e.g., Heckman et al. 2000; Shapley et al. 2003; Rupke et al. 2005; Veilleux et al. 2005; Weiner et al. 2009; Martin et al. 2012; Rubin et al. 2014). Gas flows are detected by measuring the blueshift (outflow) or redshift (inflow) of absorption transitions with respect to the host galaxy systemic velocity. Spectroscopy of galaxies from low to high redshifts probing cold gas ($T < 10^2 \ K$), which absorbs in Na I and cool gas ($T \sim 10^3 \ K$) absorbing Mg II has revealed outflows in most galaxies that host active star formation (e.g., Chen et al. 2010; Martin et al. 2012; Rubin et al. 2014). However, while this technique is useful for constraining the radial velocity, column density, and covering fraction of the flow, it weakly constrains the overall radial extent and provides little information on the morphology of the gas.

An alternative method that can in principle assess the radial extent and morphology of outflows is to trace the gas in emission. This has been demonstrated using rest-frame optical transitions (i.e., Hα, [O III]) as tracers for winds around nearby starbursts (e.g., Heckman et al. 1990; Lehnert et al. 1999; Veilleux et al. 2003; Matsubayashi et al. 2009), as these transitions are sensitive to the warm shock-heated phase of the gas. Another transition potentially useful for tracing winds in emission is the Mg II $\lambda\lambda$2796,2803 doublet in the rest-frame ultraviolet (UV; e.g., Weiner et al. 2009; Kornei et al. 2013). While most studies of winds using Mg II have focused on its absorption kinematics, Rubin et al. (2011) observed strong Mg II emission with a P-Cygni line profile in the Keck/Low Resolution Imaging Spectrometer (LRIS) spectrum of a strongly star-forming galaxy at redshift $z = 0.694$. In addition, the emission was spatially extended beyond the galaxy continuum, permitting the first direct measurement of the extent of an outflow ($>7 \ kpc$) in the distant universe.

One proposed production mechanism for such P-Cygni profiles is photon scattering. In this mechanism, Mg II ions in the region of the wind closest to the observer will absorb continuum photons in the resonant transitions at wavelengths 2796.35 Å ($\lambda_{2796}$) and 2803.53 Å ($\lambda_{2803}$) (Morton 2003). Once these transitions are excited, they may only decay back to the ground state. If the optical depth of the gas is high, then the gas will resonantly trap the absorbed photons. Because the photons are absorbed in the rest frame of the gas, the absorption is observed to be blueshifted relative to the galaxy’s systemic velocity. The Mg II ions in the section of the wind farthest from the observer will absorb and scatter photons that are redshifted relative to the front portion of the wind. Because the photons are redshifted, the photons travel freely toward the observer.
through the wind to produce emission at and redward of the systemic velocity of the galaxy (e.g., Prochaska et al. 2011; Rubin et al. 2011).

Since the first detection of Mg II emission in an individual galaxy by Rubin et al. (2011), another detection was reported by Martin et al. (2013), who observed Mg II emission that extends 12–18 kpc from a strongly star-forming galaxy at z = 0.9392. Mg II has also been studied in galaxy surveys conducted with Keck/LRIS, the Keck DEep Imaging Multi-Object Spectrograph (DEIMOS), the VLT Multi Unit Spectroscopic Explorer (MUSE), and the MMT Blue Channel Spectrograph (Weiner et al. 2009; Erb et al. 2012; Kornei et al. 2013; Feltre et al. 2018; Henry et al. 2018). These surveys, which include galaxies with redshifts 0.20 < z < 2.30, find that Mg II may be detected in pure emission, pure absorption, or with P-Cygni profiles, and that detections of Mg II in emission were found to be more commonly associated with galaxies of lower stellar mass and with bluer spectral slopes.

The diversity of these spectral profiles may be understood using radiative transfer modeling of galactic winds. Prochaska et al. (2011) have used this technique to predict spectra for the Mg II and Fe II fine-structure transitions for a variety of wind morphologies. The authors demonstrated that isotropic, dust-free winds will conserve photon flux, thus predicting that blueshifted absorption lines should be accompanied by emission lines with similar equivalent widths (EWs). Anisotropic winds, however, were demonstrated to exhibit significantly weaker emission by a factor proportional to the angular extent (i.e., solid angle) of the wind. Scattered emission was found to be additionally weakened by the inclusion of dust and the presence of a strongly absorbing interstellar medium (ISM). Thus, spatially resolved measurement of the surface brightness (SB) of this emission constrains not only the radial extent of the emitting material, but also its morphology and dust content.

In this paper, we present the first narrowband imaging of the Mg II transition around five star-forming galaxies located in the Great Observatories Origins Deep Survey South (GOODS-S; Giavalisco et al. 2004) field at redshift z ~ 0.7. We use two filters: a “line filter” covering the Mg II doublet in the observed frame, and a “continuum filter” that is offset from the line filter by ~47 Å. The resulting imaging in each filter has a total integration time of 10 hr. As opposed to slit or fiber spectra, the narrowband imaging fully constrains the SB and projected radial extent of the wind. These observations allow us to create the first ever high-S/N spatially resolved map of both detection limits on Mg II emission and on Mg II absorption.

In Section 2 we describe our sample of GOODS-S galaxies, supplemental Keck/LRIS spectra, as well as our VLT/FORS2 observations, image reduction, and absolute flux calibration. We describe our method of continuum subtraction in Section 3.

Analysis of these data is presented in Section 4, including our methods for calculating SB profiles and detection limits for each galaxy, as well as maps of Mg II EWs. Section 5 presents results from this analysis. We compare our SB detection limits to previous detections of extended Mg II emission, and compare our observations to predictions made using radiative transfer models in Section 6. We conclude this paper in Section 7. We adopt a ΛCDM cosmology with $h_0 = H_0/(70 \text{ km s}^{-1} \text{ Mpc}^{-1})$, $\Omega_M = 0.3$, and $\Omega_\Lambda = 0.7$. In this cosmology, $1^\prime$ is ~7 kpc at $z \sim 0.7$.

2. Observations and Data Reduction

2.1. Sample Selection

Our target galaxies were selected from a Keck/LRIS survey of UV absorption lines in $\approx 100$ objects having redshifts 0.3 < z < 1.4 and rest-frame B-band magnitudes $B_{AB} < 23$ in fields with deep Hubble Space Telescope/Advanced Camera for Surveys (HST/ACS) imaging (Rubin et al. 2014). In particular, this parent survey targeted galaxies in a total of nine Keck/LRIS pointings located in both of the GOODS fields (Giavalisco et al. 2004) and the AEGIS survey field (the Extended Groth Strip; Davis et al. 2007). In inspecting the redshift distribution of the portion of this sample observable from the Southern Hemisphere, we uncovered a narrow peak of nine galaxies in the interval 0.66 < z < 0.68. This peak is in fact the global maximum of the distribution, as all other bins of width $\Delta z = 0.02$ have at most four galaxies. Moreover, there are two narrow interference filters available on VLT/FORS2 centered at $\lambda = 4675$ Å and 4722 Å which cover the Mg II $\lambda \lambda 2796, 2803$ transition in precisely this redshift interval. We selected our final sample of five of these galaxies to be close on the sky such that they could be imaged in a single $7^\prime \times 7^\prime$ FORS2 pointing. We show color HST/ACS images of these objects in Figure 1.

The Bayesian absorption line modeling presented in Rubin et al. (2014) indicates that these five galaxies are driving strong outflows traced by Mg II with maximum outflow velocities $\Delta v_{\text{max}} \sim 150$–420 km s$^{-1}$ and rest-frame EWs ~2–3 Å. These maximum outflow velocities (listed in Table 1) are determined from fitting a two-velocity component model to the absorption line profiles. The two-component model assumes that there is an absorption component due to stellar atmospheres and the ISM with a velocity fixed at systemic, as well as a “flow” absorption component with a velocity that is allowed to float. The maximum outflow velocity $\Delta v_{\text{max}}$ is the fitted central velocity of the flow component, $v_{\text{flow}}$, minus the fitted Doppler parameter, $b_\text{flow}/\sqrt{2}$. It is thus indicative of the most extreme flow velocities traced by each absorption line profile. The two-component model does not explicitly include a contribution to
the line profile from scattered emission, which can be significant at velocities close to systemic (Prochaska et al. 2011). However, as discussed in Rubin et al. (2014), it is expected that scattered emission will primarily tend to reduce the strength of the fitted systemic component, and will have a minor effect on fitted flow component velocities and line widths (see their Appendix C).

Modeling of the galaxy broadband spectral energy distributions (SEDs) obtained from multi-wavelength ancillary imaging data, also performed by Rubin et al. (2014), yields SFRs ranging from ~4 to 40 $M_\odot$ yr$^{-1}$ and stellar masses in the range log $M_\star/M_\odot$ ~ 9.9–11.0. All of these sample properties as well as target coordinates are listed in Table 1.

Table 1

| Object        | z        | SFR (M_\odot yr^{-1}) | log(M) (M_\odot) | $\Delta v_{max}$ (km s^{-1}) | EW_{H\alpha} (Å) | rv^\ast |
|---------------|----------|------------------------|------------------|-------------------------------|-----------------|--------|
| J033225.26–274524.0 (J.26) | 0.6660   | 9.1$^{+3.3}_{-1.3}$    | 9.86$^{+0.00}_{-0.04}$ | $-187^{+12}_{-16}$            | 7.5 ± 0.4       | 1.227 ± 0.54 |
| J033229.64–274242.6 (J.64) | 0.6671   | 40.5$^{+12.2}_{-2.1}$  | 10.30$^{+0.03}_{-0.02}$ | $-378^{+12}_{-12}$            | 13.2 ± 0.3      | 3.897 ± 0.93 |
| J033230.03–274347.3 (J.03) | 0.6679   | 3.8$^{+18.0}_{-0.0}$    | 10.91$^{+0.01}_{-0.09}$ | $-400^{+132}_{-14}$          | 12.8 ± 1.7      | 0.297 ± 0.0 |
| J033230.57–274518.2 (J.57) | 0.6807   | 12.6$^{+17}_{-3.1}$     | 10.48$^{+0.07}_{-0.09}$ | $-266^{+44}_{-38}$            | 6.1 ± 0.4       | 1.262 ± 0.40 |
| J033231.36–274725.0 (J.36) | 0.6669   | 10.5$^{+1.6}_{-1.6}$    | 10.02$^{+0.03}_{-0.03}$ | $-168^{+126}_{-126}$         | 5.8 ± 0.5       | 1.377 ± 0.23 |

Notes. The EW in the observed frame includes both components of the Mg II doublet and is determined from analysis of the supplemental Keck/LRIS spectra. The uncertainty intervals reported for SFR, log $M_\star/M_\odot$, and rv^\ast values indicate the ±34th-percentile values of the posterior probability distribution function of each quantity as determined via modeling of the objects’ SEDs with MAGPHYS (da Cunha et al. 2008, 2012) as described in Rubin et al. (2014).

V. Galaxy names include their R.A. and decl. in the J2000.0 epoch. The names in parentheses are used to identify each object throughout the paper.

B Maximum outflow velocity traced by Mg II, $\Delta v_{max} \approx v_{flow} - b_{D,flow}/\sqrt{2}$, where $b_{D,flow}$ is the fitted Doppler parameter and $v_{flow}$ is the fitted central velocity of the “flow” component in a two-component model of the absorption line profile.

Total V-band optical depth of dust attenuating light from the young stellar population in each galaxy as modeled by MAGPHYS. This includes contributions from dust in both H II regions and the ambient ISM.

2.2. VLT/FORS2 Observations

Our narrowband imaging data were taken in service mode using the FORS2 instrument on the VLT 8.2 m telescope Antu between 2012 October and 2013 February. We used two narrowband filters, He II + 47 and He II/3000+48, that have peak transmission at wavelengths that correspond to the Mg II doublet lines at our sample redshift of $z$ ~ 0.7 (see Table 2). The filter transmission curves are plotted along with each galaxy’s spectrum in Figure 2. In the following, we will often refer to the He II + 47 filter as the “line” or Mg II filter and the He II/3000+48 filter as the “continuum” filter.

FORS2 has a native pixel scale of 0.125 pixel$^{-1}$ and a field of view of 7' $\times$ 7'. The data were taken with the CCD binned 2 $\times$ 2, yielding a pixel scale of 0.25 pixel$^{-1}$. Images of three pointings offset by 0.25 East/West were obtained, with individual exposure times of ~1000 s. A total of 38 exposures were taken in each filter. Our observations were carried out under photometric and thin cloud conditions (program ID: 090 A-0427A). The seeing values, given in the header of each image, were derived from zenith observations at 0.5 micron with the Paranal differential image motion monitor (DIMM; Sarazin & Roddier 1990) and include a correction for the airmass and wavelengths of the science observations, as well as a first-order correction for the larger size of the Antu mirror.

The distribution of these seeing values is shown in Figure 3. The median seeing for the images is ~0.8'. Summing the individual exposure times for each filter results in a combined exposure time of 10.0 hr each for the He II + 47 and He II/3000+48 images.

2.3. Supplemental Keck/LRIS Spectra

In addition to VLT imaging, in the present analysis we utilize galaxy spectra taken from the Rubin et al. (2014) Keck/LRIS program. A 0.69 slit width was used for all slitmask and the median FWHM resolution for the spectra is 274 km s$^{-1}$ at $\lambda_{\text{rest}} \approx 2800 \, \AA$ and 286 km s$^{-1}$ at $\lambda_{\text{rest}} \approx 2600 \, \AA$ (see Figure 2). The spectral coverage of these data extends from ~3200 to 8000 Å.

2.4. Image Reduction

The imaging data were fully reduced using custom routines written in Python. The images were first corrected by subtracting and removing the overscan region of the CCD. Then the images were bias-subtracted and flat-fielded using twilight flats. An additional flat-fielding correction was performed using night-sky flats to improve our sensitivity to faint extended emission. The night-sky flats were produced by first masking out all objects and bad pixels in the science frames, and then combining them using an average sigma-clipping algorithm. Cosmic rays and bad pixels in the science images are removed by utilizing the L. A. Cosmic algorithm (van Dokkum 2001). The astrometry solutions were calculated via Astrometry.net (Lang et al. 2010), and yield a standard deviation in the galaxy coordinates of $\sigma \approx 0^\prime.10$. Before image stacking, we ran each frame through SExtractor (Bertin et al.

---

Table 2

| Filter (Line) | $\lambda_{\text{eff}}$ (Å) | $\Delta \lambda$ (Å) | Nc | T | S |
|--------------|------------------|-----------------|---|---|---|
| He II + 47 (Mg II) | 4675.21 | 50.11 | 38 | 39596 | 2.45 |
| He II/3000+48 (Cont.) | 4722.46 | 44.82 | 38 | 39371 | 2.40 |

Notes. The widths of the transmission curves ($\Delta \lambda$) are calculated by convolving the transmission curves over the total wavelength range of each filter.

a $\lambda_{\text{eff}}$ is the effective wavelength of the filter transmission curve.

b The effective width of the filter.

c Total number of images.

d Total exposure time.

e $S$, the sensitivity of the filter, is in units of 10$^{-17}$ ergs cm$^{-2}$ s$^{-1}$.
to create a root mean square (rms) map of each science image.

The final stacked image for each filter is obtained using SWarp (Bertin et al. 1996). Each individual frame is first sky-subtracted using a background mesh size of 256 pixels, which is approximately 64″. We chose the mesh size to be large enough such that any extended emission is not mistakenly subtracted (e.g., Arrigoni Battaia et al. 2015). The frames, after background subtraction, are resampled onto a common astrometric solution using a Lanczos3 interpolation kernel. The images are weighted by the night-flat image and then average-combined to increase the signal-to-noise of any MgII emission. Additionally, SWarp generates stacked rms images by propagating the error images for each science frame. Our final stacked images in each filter are shown in Figure 4 with the target galaxies indicated.

2.5. Absolute Flux Calibration

We acquired observations of the standard star GD50 from archival European Southern Observatory (ESO) calibration imaging at four independent epochs. Performing aperture photometry at each epoch and airmass, we calculated the atmospheric extinction coefficients, k, to be 0.181 mag for the HeII/3000+48 filter and 0.190 mag for the HeII + 47 filter. We perform absolute flux calibration using the methods of Jacoby et al. (1987). We first convolve the SED of the standard

\begin{align*}
F_{\lambda} &= \int \frac{L_{\lambda}}{\int L_{\lambda}} \, d\lambda \\
\text{Observed Wavelength (Å)} &= 0.0 \text{ to } 1.0 \\
0.0 \text{ to } 1.0 \\
0.0 \text{ to } 1.0
\end{align*}
star, \( F(\lambda) \), in erg s\(^{-1}\) Å\(^{-1}\) cm\(^{-2}\), with that of the known transmission curve of the filter, \( T_i(\lambda) \). This yields \( F_i \), the total observable flux in each bandpass filter \( i \) with units of erg s\(^{-1}\) cm\(^{-2}\).

\[
F_i = \int F(\lambda)T_i(\lambda)\,d\lambda.
\]

It is not uncommon to assume that \( F(\lambda) \) is constant over the small width of the filter. However, because our filter transmission curves are sampled at wavelength intervals similar to the sampling of the spectrum of GD50 from the latest CALSPEC spectral library (Bohlin et al. 2017), we interpolate both spectra and compute the integral without the above assumption. The conversion from count rate to flux units for each filter is then given by

\[
S_i = \frac{F_i}{C10^4 \lambda},
\]

where \( k_i \) is the extinction in magnitudes per airmass, \( A \) is the airmass for each individual exposure, \( C \) is the measured count rate of the standard star, and \( S_i \) is in units of ergs counts\(^{-1}\) cm\(^{-2}\). Before image coaddition, each science image is corrected for atmospheric extinction by multiplying each frame by 10\(^4\)\( \lambda \). Next, the image is divided by the exposure time, effectively putting the image in units of counts per second. After coaddition, the images are then multiplied by the appropriate sensitivity factor \( S_i \). This puts the final images in the appropriate flux units, erg s\(^{-1}\) cm\(^{-2}\).

3. Image Subtraction

We have two goals for our study: (1) assess the SB of line emission in the Mg II transition in and around each target galaxy; and (2) spatially resolve the morphology of the strong Mg II absorption observed against the galaxy continuum. To achieve both of these goals, we must perform accurate subtraction of the continuum flux of each object from the images taken with the filter covering the targeted line emission. For four of the five galaxies in our sample, the He II + 47 image includes both line and continuum emission, and the He II 3000+48 image provides a high S/N measurement of the continuum only \( \approx 30 \) Å redward of the line emission in the rest frame. The spectral coverage of these filters is qualitatively different for the fifth galaxy in our sample (J.57). As shown in Figure 2, the Mg II transitions in this galaxy are approximately equally sampled by both of our filters. When we subtract the continuum image from the Mg II image we are effectively subtracting both Mg II emission (if present) and the continuum. We thus use this galaxy as a check on the quality of our continuum subtraction.

3.1. Spectral Correction

In preparation for continuum subtraction, we first consider whether the continuum level of each galaxy spectrum changes significantly over the passbands of our two filters. We use the supplementary spectra from Rubin et al. (2014) to fit the continuum and determine the spectral slope of each galaxy. We use the interactive fitting routine \texttt{lt_continuum_fit} from the \texttt{linetools} package (Prochaska 2016)\(^6\) to fit the continuum. We then find the total continuum flux in each filter by convolving the fitted continuum with each filter’s transmission curve. Next, we take the ratio of both integrated totals, as the ratio will indicate the scaling factor needed to correct our flux measurements prior to continuum subtraction.

Comparing these ratios between each galaxy, we find that they are equivalent to within 0.1%, with a value of 1.118. This value is equal to the ratio between the effective widths of the filter transmission curves, indicating that the spectral slope of each galaxy is approximately flat, and that the continuum level measured in the off-line filter provides an accurate measure of the continuum contribution to the online filter flux. We thus do not apply any spectral correction in the following analysis.

3.2. Continuum Subtraction

To properly continuum-subtract the image taken with the Mg II filter, we follow a prescription given by Arrigoni Battaia et al. (2015). We first determine the continuum flux density from the continuum filter,

\[
f_{\text{cont}} = \frac{F_{\text{cont}}}{\Delta \lambda_{\text{cont}}},
\]

where \( F_{\text{cont}} \) and \( \Delta \lambda_{\text{cont}} \) are the observed flux per pixel of the continuum image and the effective width of the continuum filter, respectively. With \( f_{\text{cont}} \) it is then possible to calculate the flux of any excess emission, \( F_{\text{line}} \),

\[
F_{\text{line}} = F_{\text{Mg II}} - f_{\text{cont}} \Delta \lambda_{\text{Mg II}},
\]

\(^6\) https://github.com/linetools/linetools
where \( F_{\text{Mg} \text{ II}} \) and \( \Delta \lambda_{\text{Mg} \text{ II}} \) are the observed flux per pixel in the Mg II filter and the effective width of the Mg II filter. The continuum-subtracted images of each galaxy are shown in Figure 5. These images have a uniform background and no obvious signatures of emission.

4. Analysis

4.1. SB Profiles and Limits

To test for the presence of Mg II emission, we perform aperture photometry on the continuum-subtracted images using the python library Photutils. We choose annuli with a radial thickness of 1 pixel or 0''25, such that the inner radius is \( r_{\text{inner}} = r_{\text{outer}} - 1 \) (in pixels). Each annulus is centered on the flux-weighted centroid of the galaxy. By dividing the summed flux in each annulus by the area in arcseconds we produce SB profiles for each galaxy. These profiles are shown in Figure 6.

The error in the SB is determined from the stacked rms images of each object. We adopt annuli that are identical to the annuli used to find the SB profiles for each galaxy. To calculate the variance inside each annulus, we sum the rms pixel values in quadrature, then divide by the area of each annulus.

To calculate the 1σ SB limit we follow the procedure of Arrigoni Battaia et al. (2015). We first mask out all the sources, their associated extended halos, and edge noise in both the He II + 47 and He II/3000+48 images. We then calculate the rms of the background in randomly placed 1" apertures. We convert these rms values to SB limits per 1 arcsec² aperture. We find that the 1σ detection limits (SB₁) are \( 6.332 \times 10^{-19} \text{ erg s}^{-1} \text{ cm}^{-2} \text{ arcsec}^{-2} \) and \( 5.808 \times 10^{-19} \text{ erg s}^{-1} \text{ cm}^{-2} \text{ arcsec}^{-2} \) in the He II/3000+48 and He II + 47 filters, respectively. With the 1σ detection limit, SB₁, determined for the continuum+Mg II (He II + 47) image, we define a thicker (or “extended”) annulus to be used to search for any extended Mg II emission. This annulus will have an inner radius approximately the size of the SB₁ isophotal contour for each galaxy. The outer radius is chosen to be the inner radius plus 5 pixels. With this larger annulus, we can

Figure 4. Top: stacked He II + 47 image of the galaxy sample. Bottom: stacked He II/3000+48 image of the same pointing. The exposure time of each image is \( \approx 10 \) hr. Each image shows approximately half of the total FORS2 FOV (7' × 5'), which contains the full sample of galaxies (indicated by the white arrows). East is up and north is right.
average any flux over large areas to reach lower values of SB. The mean radii of these extended apertures are 18, 18, 24 and 14 kpc from the centers of the targets J2.6, J3.6, J0.3 and J6.4, respectively. The resulting SB measurements are shown in Figure 5.

In the case of perfect sky subtraction and continuum subtraction, the 1σ SB limit for an extended source is $SB_1 / \sqrt{\text{Area}}$, where $A_{\text{arcsec}}$ is the area in arcsec$^2$ and $SB_1$ is the SB limit per 1 arcsec$^2$ aperture. However, our actual detection limits are altered by systematic errors from imperfect subtraction. Therefore, we determine the limits as follows. We first mask all the artifacts and sources in the continuum-subtracted images. Next, we generate many apertures with sizes similar to our extended annuli ($\sim$20 sq.arcsec), place them at random, and extract the fluxes, $F_{\text{src}}$, within these apertures. We then normalize the values of $F_{\text{src}}$ by dividing by $\sigma_{\text{src}}$, where $\sigma_{\text{src}} = SB_1 / \sqrt{\text{Area}}$. For perfect sky subtraction and continuum subtraction, the distribution of extracted fluxes should follow a Gaussian distribution with a standard deviation equal to $\sigma_{\text{src}}$. The distribution of $F_{\text{src}} / \sigma_{\text{src}}$ for these apertures is shown in Figure 6.

We calculate the standard deviation and mean of the distribution and find that the variance of the distribution is $\sigma_{\text{src}} = 1.1$, implying that the SB detection limit for our continuum-subtracted image is higher than $\sigma_{\text{src}}$ by a factor of 10%. We adopt $F_{\text{lim}} = \sigma_{\text{src}}$ as the 1σ upper limit on the total line flux of extended Mg II emission. The $F_{\text{lim}}$ is then $F_{\text{lim}} / A_{\text{arcsec}}$. The values of $F_{\text{src}}$ and 5$SB_{\text{lim}}$ for each galaxy are listed in Table 3.

4.2. Test of SB Limits

To show that Mg II emission with SB strengths comparable to our limits can be detected in our narrowband imaging, we simulate emission with varying intensities relative to $SB_{\text{lim}}$. For each galaxy, we assign our simulated emission a constant SB corresponding to 1, 3, 5, 10, and 20 times the 1σ SB inside the largest annulus used (i.e., the extended annulus). We assume Gaussian noise with 1σ equal to 1$SB_{\text{lim}}$. Next, we subtract the continuum in the same manner as explained in Section 3.2.

To aid in identifying the presence and detectability of extended Mg II emission we construct a so-called $\chi_{\text{smooth}}$ image for each level of simulated emission following the technique described in Hennawi & Prochaska (2013) and Arrigoni Battaia et al. (2015).

To construct the set of smoothed images, we first performed the following operation on the continuum-subtracted images:

$$I_{\text{smooth}} = \text{CONVOLVE}[\text{line} - \text{continuum}],$$

where the CONVOLVE operation indicates convolution of the Mg II images with a Gaussian kernel with FWHM = 1.5 pixels. Next, we computed the sigma image, $\sigma_{\text{smooth}}$, by convolving the propagated error image:

$$\sigma_{\text{smooth}} = \sqrt{\text{CONVOLVE}^2[\sigma^2]},$$

where the CONVOLVE$^2$ operation indicates convolution of the image with the square of the Gaussian kernel. The smoothed $\chi$ image, $\chi_{\text{smooth}}$, is then the smoothed line image, $I_{\text{smooth}}$, divided by the sigma image, $\sigma_{\text{smooth}}$.

Figure 8 shows the $\chi_{\text{smooth}}$ images for the five levels of simulated Mg II emission. We also include the $\chi_{\text{smooth}}$ image of each galaxy without any simulated emission (in the leftmost column). The galaxies are outlined by a black isophotal contour corresponding to 1$SB_1$ and the simulated emission is contained inside the extended annulus surrounding each contour. The $\chi_{\text{smooth}}$ images confirm that we should be able to detect extended Mg II emission down to a conservative level of 5$SB_{\text{lim}}$.

4.3. Equivalent Widths

Here we derive an expression to calculate the EW ($EW_{\text{Mg II}}$) of any absorption or emission features observed in our narrowband imaging. Starting from the expression for EW used in the context of spectroscopy,

$$\text{EW} = \int \left[1 - \frac{f_\lambda}{f_{\text{cont}}}\right] d\lambda,$$

where
we begin by dividing Equation (2) by the flux density of the continuum and the effective width of the online filter,

\[
\frac{F_{\text{line}}}{f_{\text{cont}} \Delta \lambda_{\text{Mg} \ II}} = \frac{F_{\text{Mg} \ II}}{f_{\text{cont}} \Delta \lambda_{\text{Mg} \ II}} - 1. \quad (6)
\]

Next, we rearrange the above expression such that we produce the argument of the integrand in Equation (5) on the right side,

\[
-\frac{F_{\text{line}}}{f_{\text{cont}} \Delta \lambda_{\text{Mg} \ II}} = 1 - \frac{f_{\text{Mg} \ II}}{f_{\text{cont}}}. \quad (7)
\]

We then approximate the integration in Equation (5) by multiplying the integrand above by the effective width of the
Figure 7. Normalized distribution of $F_{\text{src}}/\sigma_{\text{src}}$ values for random circular annuli placed on the continuum-subtracted line image. $F_{\text{src}}$ is the total flux within an aperture and $\sigma_{\text{src}}$ is the expected $1\sigma$ flux limit in the ideal case of perfect sky and continuum subtraction, i.e., $SB_{\text{src}} = \sqrt{\text{Area}}$. The red line is a Gaussian fit to this normalized distribution with standard deviation, $\sigma = 1.112$, and mean, $\mu = -0.441$. The black arrows point to the statistical significance of the flux inside the “extended annulus” of each galaxy.

Table 3

Significance of Extracted Flux and Detection Limits

| Object                | $F_{\text{src}}$(Mg II)$^a$ | $SB_{\text{lim}}$$^b$ | Area$^c$ |
|-----------------------|-----------------------------|------------------------|----------|
| J033225.26–274524.0   | 2.44(0.92)                  | 6.51                   | 21       |
| J033232.36–274725.0   | -1.40(-0.53)                | 6.51                   | 21       |
| J033230.03–274347.3   | -5.23(-1.75)                | 5.74                   | 27       |
| J033229.64–274242.5   | 1.23(0.44)                  | 6.22                   | 26       |
| J033320.57–274518.2   | -2.53(-1.00)                | 6.01                   | 18       |

Notes.

$^a$ Mg II flux is in units of $10^{-18}$ erg s$^{-1}$ cm$^{-2}$. The value in parentheses is the statistical significance with respect to $\sigma_{\text{src}}$.

$^b$ Limits are in units of $10^{-18}$ erg s$^{-1}$ cm$^{-2}$ arcsec$^{-2}$.

$^c$ Area of the extended annulus in arcsec$^2$.

online filter $d\lambda = \Delta \lambda_{\text{Mg II}}$

$$-\frac{F_{\text{line}}}{F_{\text{cont}}} = \left(1 - \frac{F_{\text{Mg II}}}{F_{\text{cont}}} \right) \Delta \lambda_{\text{Mg II}}; \quad (8)$$

such that

$$\text{EW}_{\text{Mg II}} = -\frac{F_{\text{line}}}{F_{\text{cont}}} \Delta \lambda_{\text{Mg II}}. \quad (9)$$

Using the above equation along with the continuum and continuum-subtracted images, we produce images of the observed-frame EW$_{\text{Mg II}}$. They are displayed for each galaxy in Figure 9 and show only the EWs within the $1\sigma$ SB$_1$ contours of the corresponding Mg II images (prior to continuum subtraction).

To compare our map of EW$_{\text{Mg II}}$ to the values measured from the Keck/LRIS spectra, we place 0.9 arcsec-wide slit-like apertures over each galaxy. The width and position angle of the apertures are consistent with the orientation of the slits used to obtain the spectra. Next, we determine which pixels lie outside the $1\sigma$ SB$_1$ contours and set their values to zero. Outside this contour, the EW$_{\text{Mg II}}$ values become poorly constrained due to the lack of S/N in the continuum. We then select all pixels with a S/N $\geq 1.5$ within each slit aperture and create a histogram to show the distribution of their EW$_{\text{Mg II}}$ values. The histograms are shown in Figure 9. We also compute the mean EW of these pixels and report their values in Table 4.

To assess the morphology of the Mg II absorption, we determine the projected distance of each pixel from the center of each galaxy in kiloparsecs. We plot the EW$_{\text{Mg II}}$ versus this projected distance for each galaxy in the right panels of Figure 9. Although some of the plots suggest a slight upward trend in the values of EW$_{\text{Mg II}}$ with increasing radii, we cannot be confident in this trend because of the large scatter. To better visualize the data and test the significance of the trend, we bin the data radially in bins with widths between 3 and 5 kpc. For example, in Figure 9(c), EW$_{\text{Mg II}}$ values shown for J.03 extend out to $\sim 25$ kpc (shown in black in the rightmost panel). We bin these EW$_{\text{Mg II}}$ values in 5 kpc increments. We calculate the mean and scatter of the EW$_{\text{Mg II}}$ in each bin and show these values in red in the right panels of Figure 9 and in Figure 10.

5. Results

5.1. Limits on Mg II Emission

For our sample of galaxies, we are sensitive to emission in our “extended” annuli with mean distances of 18, 18, 24, and 14 kpc from the centers of J.26, J.36, J.03 and J.64, respectively. We do not detect any significant Mg II emission at these distances around any of our target galaxies. The $\chi_{\text{smooth}}^2$ images shown in Figure 8 confirm this. A comparison of the simulated emission with the $\chi_{\text{smooth}}^2$ version of the original continuum-subtracted image, shown in the first column, similarly suggests that we do not detect any extended Mg II emission. We thus place 5$\sigma$ upper limits on the SB of Mg II emission for each galaxy in the sample, summarized in Table 3. The most sensitive detection limit using the largest area is SB(Mg II) $< 5.74 \times 10^{-18}$ erg s$^{-1}$ cm$^{-2}$ arcsec$^{-2}$, computed for the galaxy J.03.

5.2. Spatially Resolved Maps of Mg II Absorption

In this section we discuss the details of the absorption detected in our SB profiles as well as compare our EW$_{\text{Mg II}}$ measurements to those measured in the supplemental Keck/LRIS spectra.

5.2.1. Effects of Mg II Absorption on SB Profiles

Although we do not detect any extended Mg II emission, we do observe a decrement of flux, SB$_\text{abs}$, in the SB profiles of four out of five galaxies in our sample. As shown in Figure 6, absorption from Mg II ions is prevalent in the profiles at projected distances $\lesssim$5 kpc, and decreases radially outward from the maximum absorption at the center of the galaxies. In Table 4 we report for the galaxies J.26, J.36, and J.03 a maximum decrement in the SB profile due to absorption (SB$_\text{abs}$) $\approx -5 \times 10^{-18}$ erg s$^{-1}$ cm$^{-2}$ arcsec$^{-2}$. Additionally, we report for galaxy J.64 a SB$_\text{abs}$ with a significantly more negative value of $(-18.2 \pm 0.1) \times 10^{-18}$ erg s$^{-1}$ cm$^{-2}$ arcsec$^{-2}$. Finally, for J.57, the value of SB$_\text{abs} = (-1.25 \pm 1.12) \times 10^{-18}$ erg s$^{-1}$ cm$^{-2}$ arcsec$^{-2}$, and is consistent with measuring zero absorption, as expected given the redshift of this system. This measurement suggests that the quality of our continuum subtraction is satisfactory.
5.2.2. Morphology of MgII Absorption

Figure 9 shows the images, distributions, and radial projections of MgII EWs. We have zeroed out any values that lie outside the SB1 contours for each galaxy. We also impose a signal-to-noise cut, only including EWMg II values in the middle and right panels for pixels in which the continuum S/N is greater than 1.5 and which are inside each Keck/LRIS aperture, defined in Section 4.3. The mean EWMg II is computed for all pixels inside these apertures and the error is propagated in quadrature. The resulting values of the mean EW and the error in these measurements are summarized in Table 4.

Comparing our narrowband EWs with those measured from the spectra, we find agreement to within 1.6–4.6σ for galaxies J.26 and J.36, and more statistically significant differences for galaxies J.03 and J.64. We discuss possible causes for these differences below.

Given the size of the median seeing disk for these observations (FWHM ≈ 0″.8), the EWMg II values measured in adjacent pixels (each of which subtends 0″.25) are not independent, hence their errors are covariant. This covariance implies that the uncertainties in our mean EWMg II values are underestimated, such that the discrepancies between these values and those measured in our LRIS spectra are likely less significant than the tension described above.

Figure 2(c) shows the Keck/LRIS spectrum of galaxy J.03. The continuum observed near the Mg II transition has a low S/N compared to the spectra of the rest of the sample. Since the value of EWMg II depends on the level of the continuum, it may well be that our choice of continuum level in calculating the EWMg II from the spectrum is higher than the continuum level implied by our narrowband image. Such a systematic error could give rise to a higher spectroscopic EW.

Figure 2(d) shows the Keck/LRIS spectrum of galaxy J.64. This object is the brightest galaxy in the sample, and also exhibits the highest-velocity wind. This shifts the Mg II absorption profile toward the blue end of the HeII + 47 transmission curve, which could cause the signal in this filter to be dominated by the continuum level and the absorption signal to be underestimated.

As demonstrated in the right panels of Figure 9, a majority of the galaxies exhibit large scatter in EWMg II at large radii. To better understand the significance of any possible trends in these values, we compile the mean EWMg II values for all the galaxies and show their profiles in Figure 10. To account for the varying sizes of the galaxies, we normalize the radii of the bins by the approximate radius of the SB1 contour for each galaxy. Upon inspection of this figure, we see that the galaxies exhibit no statistically significant trend in the mean absorption EWMg II as a function of radius inside our 1SB1 isophotal contour, which suggests that the covering fraction of saturated Mg II absorption is approximately constant across the surface.

6. Discussion

6.1. Previous Detections of Extended Mg II Emission

Previous constraints on the brightness of scattered Mg II emission were reported by Rubin et al. (2011) and Martin et al. (2013). In Rubin et al. (2011) the authors studied emission from the starburst galaxy TKRS 4389 at z = 0.69 with a SFR of 49.8 M⊙ yr⁻¹. This emission was detected in a two-dimensional Keck/LRIS spectrum, with flux from the emission
Figure 9. Left: images of the equivalent widths $\text{EW}_{\text{Mg} II}$ inside the 1SB$_1$ contour for each galaxy (red). The white contour shows the placement and orientation of the $0''9$ wide slit used to measure the equivalent width of absorption in the Keck/LRIS spectrum of each galaxy. Middle: distribution of $\text{EW}_{\text{Mg} II}$ values in pixels with continuum $S/N > 1.5$ inside the slit aperture. Right: the $\text{EW}_{\text{Mg} II}$ values of these high-$S/N$ pixels vs. projected distance from the galaxy center are shown in black, and binned $\text{EW}_{\text{Mg} II}$ measurements are shown in red. The horizontal error bars represent the width of the radial bin used.
We have normalized the corresponding radii by the approximate size of the SB1 sample galaxies. Promean EW values are the same as those shown in the right column of Figure 9.

The mean EW values are the same as those shown in the right column of Figure 9. We have normalized the corresponding radii by the approximate size of the SB1 contour of each galaxy.

reaching \((8.0 \pm 0.4) \times 10^{-18} \text{ erg s}^{-1} \text{ cm}^{-2}\) at \(\lambda_{2796}\) and \((4.0 \pm 0.3) \times 10^{-18} \text{ erg s}^{-1} \text{ cm}^{-2}\) at \(\lambda_{2803}\) in two independent locations spatially offset from the galaxy continuum. The flux from both emission lines can be converted into two SB values by taking the average of the flux measured at each location and each transition, and dividing by a 1 arcsec\(^2\) aperture.

A second detection of extended Mg\(\text{II}\) emission is reported in Martin et al. (2013). In this study, the authors spatially resolve extended Mg\(\text{II}\) emission in the galaxy 32016857 at a redshift of \(z = 0.9392\) with a SFR of \(\sim 80 \, M_\odot \text{ yr}^{-1}\). Detected using a twodimensional Keck/LRIS spectrum, the Mg\(\text{II}\) emission extends out to \(\sim 11\) kpc, or 1\" at \(z \sim 0.94\), away from the galaxy continuum to the east. In the integrated spectrum, the observed flux in Mg\(\text{II}\) emission is approximately \(1.5 \times 10^{-17} \text{ erg s}^{-1} \text{ cm}^{-2}\) at \(\lambda_{2796}\) and \(1.0 \times 10^{-17} \text{ erg s}^{-1} \text{ cm}^{-2}\) at \(\lambda_{2803}\) to 20% accuracy. The extended Mg\(\text{II}\) component contributes up to 46% of the total integrated Mg\(\text{II}\) flux. As for TKRS 4389, we calculate a SB assuming that the total extended Mg\(\text{II}\) emission flux is \(0.46 \times 2.5 \times 10^{-17} \text{ erg s}^{-1} \text{ cm}^{-2}\) and that it covers an area of 1\" times the 1\" Keck/LRIS slit width. Figure 11 shows 5\(\sigma\) SB detection limits for each galaxy in our sample and the SB calculated for the galaxies TKRS 4389 and 32016857 versus SFR (left panel) and versus \(\log M_\text{SFR}/M_\odot\) (middle panel). These figures suggest that we should be able to detect scattered Mg\(\text{II}\) emission with strengths similar to that detected in both TKRS 4389 and 32016857 in our narrowband imaging.

### Table 4

| Object | SB\(_{abs}\) \(^a\) | \(R_{SB1}\) \(^b\) (kpc) | LRIS EW\(_{Mg\text{II}}\) \(^c\) (Å) | NB EW\(_{Mg\text{II}}\) \(^d\) (Å) |
|--------|-----------------|-----------------|-----------------|-----------------|
| J.26   | \(-5.4 \pm 1.2\) | 8               | 7.5 \pm 0.4     | 3.5 \pm 0.8     |
| J.36   | \(-5.6 \pm 0.1\) | 15              | 5.8 \pm 0.5     | 7.7 \pm 1.0     |
| J.03   | \(-4.4 \pm 0.6\) | 21              | 12.7 \pm 1.7    | 5.4 \pm 0.7     |
| J.64   | \(-18.2 \pm 0.1\) | 10              | 13.2 \pm 0.3    | 7.6 \pm 0.7     |
| J.57   | \(-1.3 \pm 1.2\) | 11              | 6.10 \pm 0.4    | \(-0.7 \pm 0.6\) |

Notes.

\(^a\) Maximum SB decrement in units of \(10^{-18} \text{ erg s}^{-1} \text{ cm}^{-2} \text{ arcsec}^{-2}\).

\(^b\) Radius of SB1 contour.

\(^c\) Measured from Keck/LRIS spectra in the observed frame. Includes both lines in the Mg\(\text{II}\) doublet.

\(^d\) Measured from narrowband images, and reported in the observed frame.

### Figure 10

Radial profile of the mean EW of Mg\(\text{II}\) absorption for four of our sample galaxies. Profiles for J.26, J.36, J.03, and J.64 are shown with small blue circles, green squares, large red circles, and cyan stars, respectively. The mean EW values are the same as those shown in the right column of Figure 9.

6.2. Possible Correlation of Mg\(\text{II}\) Emission Strength with Galaxy Properties

Taken at face value, the left panel of Figure 11 could be consistent with a positive correlation between Mg\(\text{II}\) SB and SFR. The constraints shown in the middle panel of Figure 11 are similarly suggestive of (and consistent with) a negative correlation between the SB of extended Mg\(\text{II}\) emission and galaxy stellar mass. Future observations are needed to verify these trends, and the possibility that objects with yet higher SFRs \((\gtrsim 50 \, M_\odot \text{ yr}^{-1})\) exhibit brighter extended Mg\(\text{II}\) emission. Finally, the right panel of Figure 11 shows that the galaxy with detected extended Mg\(\text{II}\) also has the highest specific SFR. If it is ultimately confirmed that low-\(M_\odot\) galaxies with the highest SFRs, or highest specific SFRs, exhibit the brightest emission, this could point to a physical link between the escape velocity of galaxies and the spatial extent and/or optical depth of wind material. Here we note that a similar trend was observed by both Erb et al. (2012) and Feltre et al. (2018) in their examination of the total Mg\(\text{II}\) emission strength versus \(M_\odot\).

A potential complicating factor in the interpretation of trends in Mg\(\text{II}\) SB with galaxy properties is the possible contribution of nebular emission to the Mg\(\text{II}\) line profiles. Recent studies by Henry et al. (2018) and Guseva et al. (2019) suggest that there may be a significant contribution from nebular emission (i.e., inferred from H\(\text{II}\) regions) to the total Mg\(\text{II}\) emission strength in some galaxies. In detail, Henry et al. (2018) reported strong Mg\(\text{II}\) emission having EW\(_{Mg\text{II}}\) \(\sim 0.4\)–9.1 Å along with negligible absorption arising in a sample of extreme compact starburst galaxies (“Green Peas”) at \(z \sim 0.2\)–0.3. Their photoionization modeling of the emission line strengths suggests that the observed Mg\(\text{II}\) emission lines can in fact be dominated by H\(\text{II}\) region emission in such low-metallicity systems (with \(Z = 0.16\)–0.32\(Z_\odot\)). They also note that higher metallicity and/or more dusty conditions will produce weaker nebular emission. Moreover, these authors find that the strength of observed Mg\(\text{II}\) emission is correlated with the escape fraction of Mg\(\text{II}\) photons, suggesting that within their sample, the galaxies with the weakest observed emission may have the strongest intrinsic nebular emission.

Therefore, our galaxies—exhibiting weaker emission in comparison to those studied by Henry et al. (2018)—might have H\(\text{II}\) regions producing significant intrinsic Mg\(\text{II}\) emission. However, our sample (along with TKRS 4389) is also \(\gtrsim 1\) dex higher in stellar mass and thus richer in both metals (by \(\sim +0.9\) dex in log O/H; Zahid et al. 2011) and dust than the Henry et al. (2018) Green Peas. While there may indeed be a nebular contribution to Mg\(\text{II}\) emission when it is observed in galaxies in this mass range, more detailed photoionization modeling is required to estimate line luminosities for the relevant physical conditions. As nebular emission is reprocessed by scattering just as continuum photons are, its presence would tend to brighten any spatially extended line component, and any trends in nebular emission line strengths with \(M_\odot\) or SFR would be reflected in the SBs of extended emission. The nebular contribution should therefore be considered by future studies...
interpreting the meaning of putative trends in extended line SB with galaxy properties.

6.3. Geometry of Scattering Material

In the context of the idealized models of cool gas outflows discussed in Prochaska et al. (2011), radiative transfer calculations predict that strong Mg II emission will always accompany the blueshifted Mg II absorption that is ubiquitously observed to trace galactic-scale winds (Weiner et al. 2009; Martin et al. 2012; Rubin et al. 2014). For isotropic and dust-free scenarios, photons are conserved, as any absorbed continuum photon is eventually re-emitted. Therefore, the total EW of both the absorption and emission features is equal to zero in such models. Assuming that our galaxies host an isotropic and dust-free wind (and that they do not produce significant nebular Mg II emission), we wish to determine how much emission is predicted to be generated by this wind, and how the SB of this emission compares to our detection limits.

To calculate the predicted emission flux we first determine the flux absorbed by Mg II ions. Using our Keck/LRIS spectra, we find the average value of the continuum near the Mg II doublet and multiply this value by the observed EW of the doublet. Then, to estimate the SB, we distribute this flux uniformly inside multiple annuli of varying sizes. These annuli all have an inner radius equal to the galaxy’s isophotal radius and successively larger outer radii. Additionally, because our SB limits are dependent on the size of the aperture used, we calculate the SB detection limits of our images inside each of the aforementioned annuli. Figure 12 shows how the predicted SB of emission varies with the spatial extent of the annulus (red octagons), as well as how the SB compares with our detection limits (thin black curve). Galaxy J.03 is excluded because the predicted SB of this emission lies above our detection limits. Under the assumption that the wind in these galaxies does in fact extend beyond the SB1 isophotal contour (at $R_{SB1} = 8–21$ kpc), the absence of the predicted emission in our narrowband imaging suggests that these galaxies do not host isotropic, dust-free winds.

6.3.1. Anisotropic, Dust-free Winds

There are many phenomena that may reduce the SB of the scattered Mg II emission so that it is consistent with our observations. One factor that can affect the observed emission strength is the morphology of the wind. Anisotropic winds were shown in Prochaska et al. (2011) to exhibit reduced emission strengths compared to isotropic winds. Direct evidence for anisotropic winds, and specifically for a bipolar morphology, has been observed in emission from cold and shock-heated gas around local starburst galaxies (e.g., Walter et al. 2002; Westmoquette et al. 2008; Strickland & Heckman 2009). Around distant galaxies, enhanced Mg II absorption along a galaxy’s minor axis (Bordoloi et al. 2011; Bouché et al. 2012; Kacprzak et al. 2012) observed toward background QSO sightlines is likewise suggestive of bipolar outflows. Furthermore, the analysis of Rubin et al. (2014) demonstrating a strong dependence of the incidence of winds observed “down the barrel” on galaxy orientation was interpreted as additional, strong evidence for such a morphology.

We now assume that the brightness of emission in our galaxies is reduced by the effect of anisotropy. For the anisotropic winds modeled in Prochaska et al. (2011), the emission is reduced by the factor $\Omega/4\pi$, where $\Omega$ is the angular extent of the wind. As Prochaska et al. (2011) noted, given that the outflow must cover most of the continuum in order to be detected in typical down-the-barrel spectroscopy, the value of $\Omega$ has an approximate lower limit of $\Omega > 2\pi$. We show the predicted SB profiles for wind emission from our galaxies assuming $\Omega = 2\pi$ with gray diamonds in Figure 12.

After reducing the SB of the expected Mg II emission by the corresponding factor of 2, we predict profiles that fall below our SB detection limits for galaxies J.26 and J.36. However, the SB profile of J.64 remains above our detection limits, suggesting additional phenomena are needed to reduce the strength of scattered emission. As discussed in Section 5, this object is the brightest in our sample and exhibits the strongest Mg II absorption, which suggests the presence of a strong ISM component. Prochaska et al. (2011) noted that Mg II photons...
can be more effectively trapped in such objects with large amounts of dusty interstellar material.

6.3.2. Anisotropic, Dusty Winds

Dust in the wind is another factor that can reduce the observed emission strength and affect the shape of the Mg II line profile. In the Prochaska et al. (2011) models that include dust in the wind material, the dominant effect is that the most redshifted emission is suppressed. The line flux is reduced by a factor of $(1 + \tau_{\text{dust}})^{-1}$, where $\tau_{\text{dust}}$ is the integrated opacity of dust.

The MAGPHYS SED modeling of the sample galaxies performed by Rubin et al. (2014) provides an estimate of the dust opacity in the ISM of each system (shown in Table 1). We make the simplifying assumption that the wind has the same dust opacity as the ISM, and predict the SBs for an anisotropic wind with this level of dust opacity using the SB reduction factor given above. These values are shown with blue triangles in Figure 12. For the galaxies J.26, J.36, and J.03, the introduction of dust reduces the predicted emission yet further below our detection limits. For galaxy J.64, in which anisotropy alone did not reduce the predicted emission below our detection limits, Figure 12 shows that a combination of dust and anisotropy is sufficient to reduce the predicted strength of scattered emission so that it is consistent with our observational constraints.

7. Conclusion

We have presented the results of a narrowband imaging search for Mg II emission around a sample of five star-forming galaxies at a redshift of $z \sim 0.70$ which are known to exhibit outflows traced in Mg II absorption. We did not detect any Mg II emission in this sample, and place upper limits on the SB in the range $\text{SB(Mg II)} < 5 \times 10^{-19} \text{ erg s}^{-1} \text{ cm}^{-2} \text{ arcsec}^{-2}$ at 5σ significance. These limits are determined within annuli with areas of ~20 arcsec$^2$, and having mean radii ranging from 13 to 24 kpc relative to the centers of each target. Our imaging also spatially resolves the strength of the Mg II absorption observed against the galaxy continua, yielding novel constraints on the Mg II absorption morphology. This absorption fully covers the galaxies from their centers out to isophotal contours defined by the 1σ depth of a continuum + Mg II image (at $R_{\text{SB1}} = 8$–21 kpc), suggesting that the absorbing gas is optically thick and completely covers the stellar disks out to this distance. Additionally, radial profiles of the mean EW$_{\text{Mg II}}$ measured for our sample galaxies suggest that the EWs are approximately constant across the galaxies’ stellar surfaces.
We compared our SB detection limits with the predictions of the radiative transfer models of Prochaska et al. (2011). If the winds in these galaxies do extend beyond the stellar disk, to ≥20 kpc, then we are able to rule out that the winds in our sample are isotropic and dust-free, as our images are sufficiently sensitive to detect the emission predicted by such models. Adopting the assumption of dusty and anisotropic winds reduces the strength of the predicted Mg II emission to lie below our detection limits. Although these limits may suggest that the winds in our sample are not isotropic and dust-free, questions linger regarding the relative roles wind anisotropy, dust content, and extent play in reducing scattered emission. Thus, deeper imaging or spatially resolved spectroscopy of Mg II will be needed to fully characterize the morphology of these winds.

R.R.V. gratefully thanks Joe Burchett, Karin Sandstrom, and Jessica Werk for enlightening discussions which improved this work. K.H.R.R. acknowledges support from the Alexander von Humboldt foundation in the context of the Humboldt Postdoctoral Fellowship. The Humboldt foundation is funded by the German Federal Ministry for Education and Research. These findings are in part based on observations collected at the European Organisation for Astronomical Research in the Southern Hemisphere under ESO programs 090.A-0427(A).
