(Received 8 July 2020; revised 14 October 2020; accepted 10 November 2020; published 2 December 2020)

Using the available data on deeply virtual Compton scattering (DVCS) off protons and utilizing neural networks enhanced by the dispersion relation constraint, we determine six out of eight leading Compton form factors in the valence quark kinematic region. Furthermore, adding recent data on DVCS off neutrons, we separate contributions of up and down quarks to the dominant form factor, thus paving the way towards a three-dimensional picture of the nucleon.

Since DVCS probes (both the initial virtual and final real photon) couple to charge, not flavor, to determine the distributions of particular quark flavors it is necessary either to use other processes with flavored probes (e.g., with meson instead of photon in the final state), or to combine DVCS measurements with different targets, like protons and neutrons. The latter method, involving processes with fewer hadronic states, is less prone to the influence of low-energy systematic uncertainties, and will be utilized in this study.

The data on proton DVCS are relatively rich, so it is the recent complementary neutron DVCS measurement by JLab’s Hall A Collaboration [8] that made the present study possible, and enabled us to separate the u and d quark contributions to the leading CFF. The Hall A Collaboration itself also tried to separate u and d quark flavors in Ref. [8], using the technique of fitting separately in each kinematic bin, but their results are somewhat inconclusive having large uncertainties. Here, we reduce significantly the uncertainties of the extracted CFFs by (i) performing global fits and (ii) using dispersion relations (DR), thus imposing additional constraints on CFFs. To keep our main results model independent, we parametrize the form factors using neural networks.

We first perform both model and neural net fits to most of the JLab 6 GeV proton-only DVCS data, demonstrating how adding DR constraints to the neural net procedure significantly increases our ability to extract CFFs. We end up with an extraction of six out of the total eight real and imaginary parts of leading twist-2 CFFs, including the CFF $C^e$, which is a major research target related to the nucleon spin structure [4]. Then, we make both model and neural net fits to JLab’s combined proton and neutron DVCS data. This enables a clear separation of $u$ and $d$ quark contributions to the leading CFF $H$.

Methods and data.—To connect the sought structure functions to the experimental observables, we use the formulas from Refs. [9,10], giving the fourfold differential cross section...
for the leptoproduction of a real photon by scattering a lepton of helicity $\lambda/2$ off a nucleon target with longitudinal spin $\Lambda/2$. DVCS is a part of the leptoproduction amplitude and is expressed in terms of four complex-valued twist-2 CFFs, $\mathcal{H}(\xi = x_B/(2 - x_B), t, Q^2)$, $\mathcal{E}(\xi, t, Q^2)$, $\tilde{\mathcal{H}}(\xi, t, Q^2)$, and $\tilde{\mathcal{E}}(\xi, t, Q^2)$. The kinematical variables are squared momentum transfers from the lepton $Q^2$ and to the nucleon $t$. Bjorken $x_B$, and the angle $\phi$ between the lepton and photon scattering planes. The dependence of CFFs on $Q^2$ is perturbatively calculable in QCD and will be suppressed in what follows.

An important constraint on CFFs is provided by dispersion relations [11], relating their real and imaginary parts. For example, for CFF $\mathcal{H}$ we have

$$\Re \mathcal{H}(\xi, t) = \Delta(t)$$

$$+ \frac{1}{\pi} \text{P.V.} \int_0^1 dx \left( \frac{1}{\xi - x} - \frac{1}{\xi + x} \right) \Im \mathcal{H}(x, t),$$

(1)

where $\Delta(t)$ is a subtraction, constant in $\xi$, which is up to an opposite sign the same for $\mathcal{H}$ and $\mathcal{E}$, and is zero for $\tilde{\mathcal{H}}$ and $\tilde{\mathcal{E}}$. This makes it possible to independently model only the imaginary parts of four CFFs and one subtraction constant. It is a known feature of any statistical inference that, with given data, a more constrained model will generally lead to smaller uncertainties of the results—a property usually called the bias-variance trade-off. So we expect that, besides easier modeling, the DR constraint will result in more precise CFFs. The application of this constraint to neural network models is the important technical novelty of the fitting procedure presented here.

**Model fit.**—Although the main results of this study are obtained using neural networks, for comparison we also perform a standard least-squares model fit. We use the “KM” model parametrization described in Refs. [12,13], which is of a hybrid type: Flavor-symmetric sea quark and gluon GPDs are modeled in the conformal-moment space, evolved in $Q^2$ using leading order (LO) QCD evolution, convoluted with LO coefficient functions, and added together to give the total sea CFF. On the other hand, valence quark GPDs are modeled as functions of momentum fractions, and by essentially modeling only the imaginary part of the corresponding CFF, where evolution is neglected. Additionally, $\Re \tilde{\mathcal{E}}$ is modeled by pion pole exchange, as described in Ref. [14]. Model parameters were previously fitted to proton-only DVCS data. In this work we first make a refit of this same model, adding also the 2017 Hall A proton data to the dataset. The resulting updated fit, named $\text{KM}20$, is the only model presented in this Letter which is truly global in the sense that it successfully describes also the low-$x_B$ HERA DVCS data. Then, focusing on flavor separation, we construct a model using the same flavor-symmetric sea, but parametrizing separately $u$ and $d$ valence quark contributions, and fitting to both proton and neutron DVCS data, where isospin symmetry is assumed. Since neutron datapoints are few and coming only from JLab, this flavor-separated fit is performed only to JLab data because only in this kinematics there is hope to tell flavors apart. The resulting flavor-separated fit is named $\text{fKM}20$.

**Neural networks fit.**—For the neural network approach, we use the method originally developed by two of us in Ref. [15], and inspired by a similar procedure for PDF fitting [16]. CFFs are parametrized as neural networks, with values at input representing kinematical variables $x_B$ and $t$, and values at output representing imaginary or real parts of CFFs. Here we make significant improvements by adding the possibility of DR constraints, where outputs represent only imaginary parts, and one network output represents the subtraction constant $\Delta(t)$ from (1), see Fig. 1. The iterative analysis proceeds in several steps. The network output is used as input for the DR and the result in turn as input for the cross section formulas. From comparison with experiment we then obtain the required correction, which is back propagated to the neural network. The network parameters are finally adjusted in a standard cross-validated learning procedure. For this, we modified the publicly available nYbrAI software library [17]. This DR-constrained neural net fitting procedure was already applied by one of us recently to the specific study of

![Architecture of neural nets when DR constraints are](image-url)
pressure in the proton [18], but is applied here for the first time in a more general context.

To propagate experimental uncertainties, we used the standard method of fitting to several replicas of datasets [16], generated by Gaussian distributions corresponding to uncertainties of the measured data. To determine the needed number of replicas to generate and, consequently, the number of neural nets to train, we made preliminary studies with reduced datasets, where we compared the results obtained with 10 replicas with those obtained with 80 replicas and we found that the variation of results is less than 5%, which we consider acceptable. Since training of neural nets with DR constraints is quite slow, due to the evaluation of a numerical Cauchy principal value integral [Eq. (1)] in each training step, we opted to generate our neural nets with DR constraints is quite slow, due to the evaluation of a numerical Cauchy principal value integral [Eq. (1)] in each training step, we opted to generate our results with 20 replicas for each presented model.

Similar preliminary analyses demonstrated that we do not need many neurons to successfully describe the data, most likely due to the CFF functions being quite well behaved in this kinematics. Actual numbers of neurons in our nets are given in the caption of Fig. 1.

Preliminary fits using all of the 8 real and imaginary parts of leading twist-2 CFFs have shown that $\Re q^2$ and $\Re \tilde{q}$ are consistent with zero and have negligible influence on the goodness of fit, i.e., they cannot be extracted from the present data. This is consistent with findings of Ref. [19], which used an even larger dataset. Thus, to simplify the model and further reduce the variance, we removed these two CFFs and performed all neural network fits presented below using just the remaining six CFFs.

First, to assess the influence of DR, we made fits to the proton-only DVCS data using two parametrizations 1. Using neural network parametrization of four imaginary parts of CFFs, and of the subtraction constant, while $\Re q^2$ and $\Re \tilde{q}$ are then given by DR (1)—this gives us the model NNDR20.

After we convinced ourselves that the DR-constrained neural net parametrization works in the proton-only case, we made a separate parametrization for two light quark flavors (essentially doubling everything) and fitted to the combined proton and neutron DVCS data—this gave us the model $\Re NNDR20$.

Experimental data used.—For the neural network fits we used the JLab DVCS data listed in Table I. We excluded the lower-$x_B$ HERA data because we wanted to be safe from any $Q^2$ evolution effects since QCD evolution is not yet implemented in our neural network framework. Also, in order to demonstrate flavor separation, it made sense to restrict ourselves to the particular kinematic region where the neutron DVCS measurement was performed such that there is some balance between the proton and neutron data.

The data contain measurements of the unpolarized cross-section $d\sigma$, various beam and target asymmetries defined via

$$d\sigma_{\perp A} = d\sigma(1 + \Lambda_{L,U} + \Lambda_{L,U} + \Lambda_{L,L}).$$

as well as the helicity-dependent cross section $\Delta\sigma = d\sigma_{L,U}$. For consistency with our leading-twist framework, we removed the data with either $Q^2 < 1.5 \text{ GeV}^2$ or $-t > Q^2/4$. Furthermore, since formulas [9,10] describe observables as truncated Fourier series in $\phi$, with only one or two terms, we made a Fourier transform of the data, and fitted only to these first harmonics. This makes the fitting procedure much more efficient. We propagated the experimental uncertainties using the Monte Carlo method, and checked that, indeed, no harmonics beyond the second one are visible in the data with any statistical significance.

### Table I. Values of $\chi^2/n_{\text{pts}}$ for presented models and for each set of DVCS measurements with fixed proton or neutron target used in this study ($\phi$-space). First row specifies the number of real independent CFFs plus the number of subtraction constants. Second row gives total value for all datapoints in actually performed fit (which was just to leading harmonics of Fourier-transformed data—$n$-space).

| Observable | $n_{\text{pts}}$ | $\Re KM20$ | $\Re NN20$ | $\Re NNDR20$ | $\Im KM20$ | $\Im NNDR20$ |
|------------|-----------------|------------|------------|-------------|------------|-------------|
| # CFFs + $\Delta s$ | $3 + 1$ | 6 | 4 + 1 | 5 + 2 | 8 + 2 |
| Total (harmonics) | 277 | 1.3 | 1.6 | 1.7 | 1.7 | 1.8 |
| CLAS [20] $A_{LL}$ | 162 | 0.9 | 1.0 | 1.1 | 1.2 | 1.3 |
| CLAS [20] $A_{UL}$ | 160 | 1.5 | 1.7 | 1.8 | 1.8 | 2.0 |
| CLAS [20] $A_{UL}$ | 166 | 1.3 | 3.9 | 0.8 | 1.1 | 1.6 |
| CLAS [21] $d\sigma$ | 1014 | 1.1 | 1.0 | 1.2 | 1.2 | 1.1 |
| Hall A [22] $d\sigma$ | 1012 | 0.9 | 0.9 | 1.0 | 0.9 | 1.1 |
| Hall A [22] $\Delta\sigma$ | 240 | 1.2 | 1.9 | 1.7 | 0.9 | 1.3 |
| Hall A [23] $d\sigma$ | 358 | 0.7 | 0.8 | 0.8 | 0.7 | 0.7 |
| Hall A [23] $\Delta\sigma$ | 450 | 1.5 | 1.6 | 1.7 | 1.9 | 2.0 |
| Hall A [8] $d\sigma$ | 360 | 1.6 | 2.2 | 2.2 | 1.9 | 1.7 |
| Hall A [8] $\Delta\sigma$ | 96 | | | | | 1.2 |
| Total ($\phi$-space) | 4018 | 1.1 | 1.3 | 1.3 | 1.2 | 1.3 |
FIG. 3. Model fit of proton from the DVCS data possible [18, 27]. The DR-attempts at determination of quark pressure distribution in CFF. It is this particular effect of DR that made recent constrained neural net fit (first row of Table I) leads to a similar quality of fits. One different number of independent CFFs in our models (see resulting CFFs are realistic. Note that the significantly in somewhat better agreement with the model fit induces a strong dependence and a clear extraction of this CFF. For other CFFs, there is no visible separation.

Results and conclusion.—The quality of the fit for each model is displayed in Table I. Judging this quality by the $\chi^2$ values for fits of the above-mentioned Fourier harmonics of the data (second row of Table I) is problematic, because propagation of experimental uncertainties to subleading harmonics is impaired by unknown correlations, see discussion in Sect. 3.1 of Ref. [7]. We consider the values of $\chi^2$ for the published experimental $\phi$-dependent data as a better measure of the actual fit quality. These are displayed in other rows of Table I. Some particular datasets are imperfectly described, but total values of $\chi^2/n_{\text{pts}}$ of 1.1–1.3 look reasonable and give us confidence that the resulting CFFs are realistic. Note that the significantly different number of independent CFFs in our models (see the first row of Table I) leads to a similar quality of fits. One concludes that there are some correlations among CFFs. Some are intrinsic, like the consequence of DR, while some will be broken with more data, on more observables.

On Fig. 2 we display CFFs for models KM20, NN20, and NNDR20 obtained from fits to proton-only data. We observe the power of DR constraints, which lead to reduced uncertainties of the NNDR20 model in comparison to NN20, most notably for $\Im H$ and $\Re H$, and $\Im E$ and $E$, where DR constraints can even change the sign of the extracted CFFs. (Interestingly, the popular VGG [24] and GK [25] models have negative $\Re E$, while the fit in Ref. [26] gives a positive $\Re E$ in this region.) For $\Re H$, DR induce a strong $\xi$ dependence and a clear extraction of this CFF. It is this particular effect of DR that made recent attempts at determination of quark pressure distribution in the proton from the DVCS data possible [18, 27]. The DR-constrained neural net fit NNDR20 is, as is to be expected, in somewhat better agreement with the model fit KM20 which is also DR constrained. The green bands in the second row of Fig. 2 constitute the first unbiased extraction of the important CFF $E$ in this kinematic region.

The CFFs in the NNDR20 model are in broad agreement with the results of the (also DR-constrained) model fit of Ref. [26]. One notable exception is the opposite sign of $\Im E$. As this CFF has the largest uncertainty of the six displayed, one can hope that with more data the discrepancy will fade. Comparing with CFFs extracted by the recent global neural network fit of Ref. [19], results agree within specified uncertainties, with the largest tension now being observed for $\Re E$. One notes that $\Re E$ of Ref. [19] agrees much better with our fit NN20, which is to be expected since one is now comparing results of more similar procedures: both are completely unbiased fits, with neither using DR constraints.

Turning now to the simultaneous fit to proton and neutron data, besides in Table I, the quality of the fit can also be seen in Fig. 3, where the model fit KM20 and the DR-constrained neural net fit NNDR20 are confronted with Hall A data. The resulting $\Re H$ and $\Re E$ CFFs, separately for up and down quarks, are displayed in the right two panels of Fig. 4, demonstrating how the inclusion of neutron DVCS data enables a clear flavor separation for this CFF. For other CFFs, there is no visible separation. The separated up and down quark CFFs have much larger uncertainties than their sum, shown in the left panels of Fig. 4, and although there are some hints of different $t$ slopes, at this level we are not yet able to address the...
question of possible different spatial distributions of up and down quarks in the nucleon.

To conclude, we have used JLab DVCS data to make both a model-dependent and an unbiased neural net extraction of six Compton form factors, where constraints by dispersion relations proved valuable. Furthermore, in the case of the dominant CFF $H$, we have successfully separated the contributions of up and down quarks. This constitutes another step towards a full three-dimensional picture of the nucleon structure.

In the interest of open and reproducible research, the computer code used in the production of numerical results and plots for this Letter is made available in Ref. [28].
