\textbf{ABSTRACT}

We present optical spectroscopy, B,V,R and I CCD photometry and VLA neutral hydrogen observations of the interacting quartet NGC 6845, also known as Klemola 30. NGC 6845 A, the dominant component, sports a broad and bright tidal bridge and a faint tidal tail, which bifurcate. The tidal bridge has a (B-I) color bluer than that of NGC 6845 A inner disk. Five strong condensations, identified as H\textsubscript{ii} regions brighter than the brightest one known in our Galaxy, are found along the tidal bridge, with the two most luminous located at the bridge tip. Two giant H\textsubscript{ii} regions, comparable to 30 Dor, are located where the tidal bridge and the tidal tail joint the disk of NGC 6845 A. Since the age of the H\textsubscript{ii} regions is 3-8 Myr, star formation has been occurring along the tidal bridge and in the tidal arm well after they had begun to be torn apart ($\geq$100 Myr). Satoh model fitting to the optical rotation curve of the A component reveals a kinematical mass of $4.4 \pm 1.2 \times 10^{11} \, M_{\odot}$, inside the central 12 kpc ($H_0 = 75 \, \text{km} \, \text{s}^{-1} \, \text{Mpc}^{-1}$). The H\textsubscript{i} emission consist of two components, a more massive one that belongs to NGC 6845 A, and a second one associated to NGC 6845 B. We do not detect gas associated to galaxies C and D. The total amount of H\textsubscript{i} is $1.4 \times 10^{10} \, M_{\odot}$, five time higher than the H\textsubscript{i} content of the Milky Way. The H\textsubscript{i} kinematics indicates an amount of dark matter associated to the A component two times higher than the mass inside its central 12 kpc. The group kinematics indicates an $M/L \approx 43(\pm 2) \, (M/L)_{\odot}$ or $M/L \approx 66(\pm 2) \, (M/L)_{\odot}$, according to two different prescriptions for the internal absorption correction. In spite of this large difference, both values furnish similar group mass ($\approx 1 \times 10^{13} \, M_{\odot}$). Although preliminary results on N-Body simulations indicate that either B or C might well create a tidal feature like the bridge of the A component, the collision with B appears to be more favourable.

\textit{Subject headings:} galaxies: fundamental parameters — galaxies: individual (NGC 6845) — galaxies: interactions — galaxies: kinematics and dynamics — galaxies: photometry

1. Introduction

Two decades ago, Toomre and Toomre (1972) demonstrated through numerical models that gravitational interactions between galaxies can generate spectacular tidal features. In earlier work, Zwicky (1956) already proposed that collisions between giant galaxies may result in the ejection of stars and gas into the intergalactic space, resulting in the formation of star clusters and star forming dwarf galaxies. Direct observational evidence for the existence of such a class of recycled galaxies has already been reported in the literature (e.g. Schweizer 1978). Systems like the Antennae (Schweizer 1978; Mirabel, Dottori, and Lutz 1992) and the Super–antennae (Mirabel, Lutz and Maza 1991) show, in addition to stellar material and gas torn from the disks of the interacting galaxies, optically bright clumps along and at the extremes of the tidal tails as well. In some cases there is even a chain of knots of bright material whose colors become bluer towards the tips (Hibbard et al. 1994). Radio observations of these systems have shown that a large amount of atomic hydrogen is torn away from the parent galaxies, stretched along the tidal tails, and seems to concentrate at the tips. In contrast, molecular hydrogen is concentrated in the central regions of the parent galaxies. A particularly nice example is the interacting galaxy Arp 105 (Duc and Mirabel 1994; Duc et al. 1997), that shows near the end of its tidal tail a LMC–like galaxy, resulting from the collision of a spiral with an elliptical galaxy.

It is well known from numerical simulations that the form and strength of the tidal bridges and tails depend on the orbital and spin parameters of the colliding galaxies (e.g. Toomre and Toomre 1972; Wright 1972; Eneev, Kozlov and Sunyaev 1973; Negroponte and White 1983; Barnes 1988). However, the star formation activity within the tidal tails could only recently be numerically studied, after the development of appropriate codes (e.g. Hernquist and Katz 1988; Elmegreen, Kaufmann and Thomasson 1993). Models that do not take into account the gas, or the fact that the H\textsubscript{i} is distributed predominantly at the periphery of spirals, are unable to reproduce the observed distribution after a collision (Barnes and Hernquist 1992), while those that do take this into account find that, after a collision with a massive body, the gas can form huge pools at the extreme ends of the tidal tails (Elmegreen, Kaufmann and Thomasson 1993).

In this paper we study the group NGC 6845 (Klemola 30, AM 1957-471). Klemola (1969) described the group as being compact, dominated by a bright, one–armed spiral. In the Arp and Madore (1987) catalogue, NGC 6845 is described as an interacting quartet. Its four components are approximately aligned in a SW–NE direction. The components NGC 6845 A and NGC 6845 B, the later located to the NE, show abundant signs of an ongoing interaction, such as tidal bridges and tails. Many clearly defined knots dot the tidal bridge that links NGC 6845 A to NGC 6845 B. Signs of interaction seem also to be present in NGC 6845 C and NGC 6845 D, according to Graham and Rubin (1973) and Rose and Graham (1979) sketches. In order to study the collision kinematics and the subsequent process of star formation, we carried out optical imaging and spectroscopy as well as radio synthesis observations.

In Section 2 we show our optical and radio observations of NGC 6845 and briefly describe the data reduction; in Sec. 3 we present our analysis; two possible scenarios for the interaction process are discussed in Sec. 4 and in Sec. 5 we summarize our results and present our conclusions.

2. Observations and data reduction

Table 1 presents some basic data on NGC 6845. Our observations consist of optical broadband photometry and spectroscopy obtained at the CASLEO\textsuperscript{3} and Bosque Alegre\textsuperscript{4} observatories and H\textsubscript{i} observations taken with the Very Large Array.\textsuperscript{5} Tables 2 and 3 list the relevant instrumental and observational parameters. We adopted $H_0 = 75$ km s\textsuperscript{-1} Mpc\textsuperscript{-1} throughout this paper, which results in a distance to NGC 6845 of 85 Mpc.

\textsuperscript{3}Complejo Astronómico El Leoncito is operated under agreement between the Consejo Nacional de Investigaciones Científicas y Técnicas de la República Argentina and the Universities of La Plata, Córdoba and San Juan.

\textsuperscript{4}Estación Astrofísica de Bosque Alegre is operated by Observatorio Astronómico of the Universidad Nacional de Córdoba, Argentina.

\textsuperscript{5}The VLA is a facility of the National Radio Astronomy Observatory which is operated by Associated Universities, Inc., under cooperative agreement with the National Science Foundation.
At this distance, 1 arcsec corresponds to 412 pc. The observations are described in more detail below.

2.1. Optical images

Broad-band B, V, R and I CCD images were obtained in September 1997 with the Ritchey–Chrétien 2.15–m telescope at CASLEO, Argentina, using a thinned Tektronix 1024 × 1024 pixel CCD detector. The telescope focal ratio is f/8. The final image scale, with a focal reducer, is 0.81 pixel−1. The seeing during the observations varied between 2″ and 4″5. Data reduction was performed with IRAF, using standard procedures. Different frames taken through the same filter were registered to a common center, using field stars as a reference, and co-added to remove cosmic ray events and increase the dynamic range. Small seeing differences among frames were corrected by gaussian filtering. Flux calibration was based on standard stars from Landolt (1992). We corrected as usual for atmospheric extinction.

2.2. Optical spectroscopy

Long–slit spectroscopic observations were carried out on July 1994 (seeing = 1″7) and September 1997 (seeing = 2″) with the 2.15 m telescope of the CASLEO observatory, and on December 1997 with the Bosque Alegre 1.52 m telescope (seeing = 1″5). In Table 3 we present the log of the spectroscopic observations. The slit positions, given in the first column of this table, are marked in Figure 5.

Data processing was again done with IRAF following standard methods for bias subtraction, flat–fielding, and image combination. The resulting two dimensional spectra were wavelength calibrated using HeNeAr comparison spectra and flux calibrated using spectrophotometric standard stars from Stone and Baldwin (1983). Galactic extinction was corrected with the standard absorption law, adopting $A_B = 0.16$ (Burstein and Heiles 1984).

2.3. VLA radio–observations

VLA D–array observations of the NGC 6845 system were obtained during a short, 1.5 hour run in 1996, June 19. Due to its far southern declination the synthesized beam is substantially elongated in the N–S direction. The beam measures 112″ × 37″, at a +14.5° angle measured from North to East. The sensitivity of the system was rather modest and the HI data should be seen as exploratory. As it was not obvious at what velocities HI could be expected we aimed for velocity coverage rather than for velocity resolution, trying to maximize our sensitivity for the velocity range expected for objects A and B (radial velocities are given in Tab. 1). The velocity resolution was 43.1 km s−1, covering the interval 6450 km s−1 to 6900 km s−1 with both right–hand (R) and left–hand (L) polarization; the intervals from 6000 km s−1 to 6450 km s−1 and 6900 km s−1 to 7050 km s−1, were observed with one polarization only. Data calibration and mapping was performed with AIPS. The final maps have an RMS noise of 1.6 mJy beam−1 or 0.23 Kelvin (where 1 mJy beam−1 corresponds to 0.15 K).

3. Results

3.1. Optical morphology and photometry

We present in Figure 1 the R image, enhancing the lowest surface brightness levels in order to highlight the faint details that might have been produced by the interaction. Clear indications of strong collision are observed in NGC 6845 A and NGC 6845 B. The tidal bridge between galaxies A and B present a fainter counterpart, a tidal tail that bifurcate and seems to connect to components C and D (see sketches in Graham and Rubin 1973 and Rose and Graham 1979 and Plate I in Rose 1979).

In Table 4 we present the integrated B magnitude and colors (B-V), (V-R) and (V-I) of the group members. As can be seen from Tab. 1, our B magnitudes are in better agreement with Rose and Graham (1979) than with RC3. The (B-I) color map (Fig. 2) shows that the color of the tidal bridge is bluer than the inner disk of A and B components and comparable to their outer disks. Hibbard et al. (1994) pointed out that in the case of the evolved merge NGC 7252 the tidal tails are 0.2–0.5 mag bluer in (B-R) than the outer regions of the main body.

NGC 6845 A is classified as SB(s)b (RC3). The color distribution along its bar is not uniform. To the SW, the bar is much redder, indicating that on this side we are seeing dust in front of the stellar
bar, where it is usually accumulated in more or less linear shock fronts. The bar of NGC 6845 A is shifted by 30° counterclockwise with respect to the photometric major axis, and it may have been tidally created by the encounter, as suggested for example by Barnes (1988) or Salo’s (1991) simulations of disk-disk encounters.

Plumes and small condensations are evident around NGC 6845 B, and are likely debris of the tidal interaction. The tidal bridge linking the NGC 6845 A and B galaxies is very pronounced in the middle of the tidal bridge, have Hα luminosities comparable to that of NGC 3603, the most luminous HII region known to exist in our galaxy (L_Hα = 1.1 x 10^40 erg s^-1, Melnick, Tapia and Terlevich 1989) or higher. Regions 4 and 5, at the tip of the tidal bridge are even brighter, being similar to 30 Doradus (L_Hα = 6.3 x 10^40 erg s^-1, Kennicutt, Edgar, and Hodge 1989). Giant HII regions near the ends of tidal bridges and tails were reported for various systems, as in NGC 6746 by Stockton (1974) and in NGC 2623, NGC 6621/22, NGC 3256 and NGC 3535/36 by Schweizer (1978). These ionising clusters are usually more luminous than the ones along the tidal tails. Finally, HII regions 7 and 8, located at the extreme ends of the bar in NGC 6845 A, have luminosities comparable to the “Jumbo” HII region of NGC 3310 (L_Hα = 1.4 x 10^40 erg s^-1, Pastoriza et al. 1993), indicating a strong star formation activity in these places, which may also have been triggered by the collision (Kennicutt and Chu 1988).

Like other interacting systems, this group is prominent in the infrared. The IRAS fluxes (F_12 μm = 0.35 Jy, F_25 μm = 0.32 Jy, F_60μm = 2.78 Jy and F_100μm = 6.66 Jy; Rush, Malkan and Spinoglio 1993), lead to a group total luminosity of L_IR = 7.9 x 10^{10} L_☉, locating this group at the fainter end of Luminous IR galaxies according to the definition by Sanders and Mirabel (1996).

3.2. Knots, their brightness and colors

Table 5 shows the V magnitude and (B-V), (V-R), and (V-I) color indexes for the most conspicuous knots marked in Fig 3. Without exception the knots present an HII–region like spectrum, as shown in Figure 4, and we feel therefore confident identifying them as regions of recent star formation. In order to correct the colors for internal absorption we used for all regions the mean value of the Hα/Hβ ratio as was measured in knots 4, 7 and 8 (see Tab. 6). Hα and Hβ intensities were measured from slit positions 3 and 5 for knot 4 and slit position 4 for knots 7 and 8 (see Fig. 5). Although these regions are located at very different positions within the system, they present roughly the same Hα/Hβ ratios, so we assume a constant Hα/Hβ ratio of 4.3 to correct the other regions through the formula: A_λ = (4.85 x λ - 1.45) log (Hα/Hβ) (Osmer, Smith and Weedman 1974).

We compared the brightness and colors of the knots to the evolutionary synthesis models of Bertelli, et al. (1994), with updatings (Girardi 1999, private communication). We chose from their models those with a Salpeter IMF and a heavy element abundance Z = Z☉. In Table 5 we present the mean age of the knots obtained by fitting our three colors to Girardi’s models. Their masses were derived from the V magnitude and assuming a distance of 85 Mpc. Within the errors all the knots, except for numbers 6 and 8, are coeval to within our stated accuracy. The derived values, quoted in Table 5, imply that we are dealing with star clusters with masses ≤ 5 x 10^5 M☉.

In Table 6 we present the Hα emission–line luminosities of all the knots in Fig. 3, plus the nuclear emission of NGC 6845 A and NGC 6845 B. As can be seen, knots 1, 2 and 3, located in the middle of the tidal bridge, have Hα luminosities comparable to that of NGC 3603. The knots are HII regions, as will be shown in Sec. 3.2.

Rose’s (1979) CTIO 4m plate shows more clearly than our Fig. 1 the presence of condensations in the tidal tail, specially a set of them close to the NW side of NGC 6845 C, though it does not shows the bridge knotty structure because it is over–exposed. Based on Rose’s plate, Rose and Graham (1979) schematically suggested that NGC 6845 A western tidal tail bifurcates and links to NGC 6845 C and D galaxies.

3.3. H I gas distribution

In Fig. 6 we show the HI isodensity contours superimposed on the R–band image. Despite the low spatial resolution of the radio observations, it is possible to distinguish two velocity components that differs by a few hundred km s^-1, a main component centered on NGC 6845 A and a secondary one associated with NGC 6845 B. No HI was detected at the velocities of galaxies C and D.
The main HI component presents a clear extension towards the SW, bending South, following the stellar tidal tail. To the East, it shows a protrusion that coincides with the bright optical tidal bridge, with velocities compatible with this feature within the observational errors. The integrated HI flux of the main component is 6.79 Jy km s\(^{-1}\), which translates to an HI mass of 1.15 \times 10^{10} \, M_\odot.

The component associated with NGC 6845 B is virtually stationary in velocity. The mean velocity is around 6700 km s\(^{-1}\), close to that of NGC 6845 B. Spatially, it is slightly shifted eastward with respect to NGC 6845 B. The integrated HI flux is 1.52 Jy km s\(^{-1}\), which translates to 2.58 \times 10^9 \, M_\odot.

The total integrated HI flux of both components is 8.31 Jy km s\(^{-1}\), corresponding to an HI mass of 1.41 \times 10^{10} \, M_\odot, or about 5 times more HI than that contained in the Milky Way.

### 3.4. Kinematics

In Fig. 5 we show the slit positions along which we obtained spectra. For ease of reference we indicated in Fig. 3 the radial velocity of the more relevant objects. Radial velocities were obtained using a weighted mean of the values measured for the H\(_\alpha\), H\(_\beta\) and [OIII]\(_{\lambda\lambda5007}\) lines. A comparison with Table 1 shows that the radial velocity values we measured for NGC 6845 A and B are in agreement with previous results from Rose and Graham (1979) and RC3. There is, however, a discrepancy between the values given by the cited references for radial velocities of components C and D. Apparently one of these sources made a mistake in the galaxies identification.

#### 3.4.1. NGC 6845 A: Optical rotation curve

The rotation curve of NGC 6845 A, presented in Figure 7, was obtained from slit position 4 (see Table 3 and Fig. 5), along the apparent major axis of the galaxy. Line of sight velocity measurements were transformed to circular velocities adopting an inclination angle of 57°\((\pm3°)\), derived by fitting ellipses to the optical isophotes of the B image (using the appropriated procedure in the STSDAS–IRAF package). Since the isophotes in the inner part of NGC 6845 A are influenced by the bar profile, and those more external are tidally distorted, we adopted the ellipticity of isophotes at intermediate radii as the best indicator for the inclination. There is a marked difference between the NE and the SW sides of the rotation curve for \(r \geq 6\) kpc (see Fig. 7): to the NE it shows a strong bump at about 6 kpc, whereas the SW half presents a plateau at about the same distance. A qualitative comparison with numerical simulations (e.g. Mihos and Bothun 1997; Barton, Bromley and Geller 1999) suggests that the difference is more likely due to tidal rather than intrinsic effects, which perturb more strongly the galactic disk periphery.

The average rotation curve (Fig. 7) was fitted with Satoh’s (1980) density law:

\[
V_c^2(R, Z) = GM R^2 \left[ R^2 + Z^2 + a(a+2 \sqrt{Z^2 + b^2}) \right]^{-3/2}
\]

where \(V_c(R, Z)\) is the circular velocity at position \((R, Z)\), \(M\) is the total mass and \((a, b)\) are shape parameters with the dimension of length. Following Satoh, a ratio of \(b/a \approx 0.1\) corresponds to a disk dominated distribution, \(b/a \approx 1\) to a disk plus a well developed bulge (Sa–SO, see Satoh 1980) and \(b/a \approx 10\) to a near spherical distribution. \(\chi^2\) fitting was performed by the downhill simplex minimization algorithm (“amoeba”) with the IRAF NFFT1D task. The parameters obtained for the fit were \(a = 6.5 \pm 0.4\) and \(b/a = 0.3 \pm 0.1\), which indicates a dominant disk with a small to intermediate bulge, in agreement with RC3 classification The fit is shown in Fig. 7, where the full line represents the best fit and the dashed lines give its lower and upper limits within the observational errors, which in turn furnishes \(a\) and \(b/a\) errors. The derived model total mass is \(M_{\text{Satoh}} = 4.4(\pm1.2) \times 10^{11} \, M_\odot\). The Keplerian mass up to the last point on the rotation curve is \(3.2 \times 10^{11} \, M_\odot\), broadly in agreement with the more sophisticated fit based on Satoh’s model.

NGC 6845 A mass is comparable to that of Andromeda. Andromeda’s brightness is \(V = 3.44\) mag at a distance of 0.7 Mpc, corresponding to 13.5 mag at the distance of NGC 6845 A, and indicating that both galaxies are comparable in their M/L ratio. Nevertheless, the size of NGC 6845 A is only half that of Andromeda. This figure would be difficult to change since in order to make both galaxies comparable in size, a Hubble constant smaller than 35 km s\(^{-1}\) Mpc\(^{-1}\) would be required. It is also difficult to invoke an error in the derived mass for NGC 6845 A due to an...
error in the disk inclination since, even by assuming an edge-on position for this galaxy, we could not reduce the derived mass by more than a factor of 1.5. Graham and Rubin (1973) pointed already out that NGC 6845 A should have a large mass because of its uncommonly large maximum velocity. We note that their rotation curve extends only up to \( \sim 6kpc \).

3.4.2. Tidal bridge kinematics

It is interesting to note that the tidal bridge of NGC 6845 A shows a decreasing trend in radial velocity (see Fig 3 and Tab 6) starting from its base, where it is connected to the NGC 6845 A disk near region 8 (at 6660 km s\(^{-1}\)), and passing through H\(^{\text{i}}\)I regions 3, 2 and 1, located more or less in the middle of the tidal bridge (at 6455 km s\(^{-1}\), 6361 km s\(^{-1}\) and 6272 km s\(^{-1}\), respectively). Regions 4 and 5, which are slightly shifted to the north with respect to the prolongation of the bridge, surprisingly present radial velocities that agree with this trend (6314 km s\(^{-1}\) and 6201 km s\(^{-1}\), respectively), strongly suggesting that they are linked to the tidal bridge and not to NGC 6845 B, despite the fact that they are seen projected on top of this object. We also detected H\(^{\text{i}}\)I on the tidal bridge, with a mean velocity of 6350 km s\(^{-1}\), in agreement with the optical results (see next Section).

Supposing that the tidal bridge tip follows a parabolic orbit in the plane of NGC 6845 A disk and its present true velocity is the observed radial velocity of the H\(^{\text{i}}\)I regions 4 and 5, we obtain a collision age of \( \sim 150-300 \) Myr. Since H\(^{\text{i}}\)I regions cannot be older than 10 Myr (see Sec. 3.2), this implies that star formation activity occurs inside the tidal bridge, started well after the beginning of the bridge formation.

A possible scenario for the bridge late star formation come out from Barnes and Hernquist (1992) simulations. These authors found that self-gravitating star clumps forms along tidal tails after a collision. The gas clouds torn apart from the galactic disk simultaneously with the stars may fall into these clumps, reaching the necessary density in order to form stars. Cloud–cloud collisions inside the tidal bridge may be an alternative mechanism to explain the star formation inside the bridge.

3.4.3. H\(^{\text{i}}\)I velocity field of NGC 6845 A

The isovelocity map of the H\(^{\text{i}}\)I component associated with NGC 6845 A is shown in Fig. 8, superimposed on the R–band image.

In Fig. 9, we show the H\(^{\text{i}}\)I position–velocity diagram, obtained by cutting the data cube along the major axis of NGC 6845 A (line of the optical spectrum slit number 4 in Figure 5). In this figure the center of NGC 6845 A is at \( \delta = -47^\circ 12'30'' \) and 6399 km s\(^{-1}\). To the South of the galaxy center, the diagram shows a behavior similar to that of the optical rotation curve (Fig. 7), so we conclude that in this part the H\(^{\text{i}}\)I kinematics is mainly rotational. To the North, the lower part of this diagram shows a plateau at 6350 km s\(^{-1}\), coincident with the tidal bridge velocity. Supposing that the H\(^{\text{i}}\)I is in dynamical equilibrium, we derive from its kinematics (Fig. 8) a mass of \( 1.4 \times 10^{12} M_\odot \), about three times higher than the mass derived from the optical data. We attribute this difference to the fact that the H\(^{\text{i}}\)I can be followed out to larger distances, especially to the SW (the upper part of the position–velocity diagram of Fig. 9), and hence will trace the dark matter associated with the halo of NGC 6845 A. Nevertheless, we have to keep in mind that the H\(^{\text{i}}\)I kinematics may suffer non–rotational effects. The H\(^{\text{i}}\)I map low spatial resolution does not allow to see the classical butterfly diagram, characteristic of 2-D rotational maps. As can be seen in Figure 8, the isovelocity lines are roughly oriented along the beam major axis.

3.4.4. The group kinematical mass

Following Binney and Tremaine (1987), equation 10–21), the radial velocity difference among the system members, their absolute luminosities (Tab. 4) and projected positions, allow us to derive the group M/L ratio. For the group member velocities we adopt the mean value of the available data (Rose and Graham 1979; RC3 and ours, see Tab. 4).

An important source of error in determining M/L is the high inclination of the C component and, to a less extent, that of the A component, the group most massive galaxies. The inclination of each group member was obtained as quoted in Sec. 3.4.1 for NGC 6845 A. Holmberg’s (1958) correction was applied to the measured isophotal
axis ratio $b/a$ by the formula $\cos^2(i) = \frac{(b/a)^2 - q_0^2}{1 - q_0^2}$ in order to obtain the galaxies’ inclinations (see Tab. 4), where $q_0 = 0.2$ (Kodaira and Watanabe 1988). This correction is specially important for NGC 6845 C. We obtained for this galaxy $b/a = 0.22 \pm 0.05$, measured at the isophotal level 25 mag/arcsec$^2$. Galactic extinction was corrected with the standard absorption law (Burstein and Heiles 1984). In order to obtain the galaxies face-on magnitudes we corrected internal absorptions by the empirical (RC3) formula $A(i) = A(0) + \alpha \log \sec(i)$, which was evaluated following two different prescriptions of the values of $A(0)$ and $\alpha$. The first one is from Rubin et al. (1982), where $A(0) = 0$ and $\alpha = 1.9$, leading to $(M/L)_1 = 43.5 \pm 2.0$ (solar units), with the uncertainties estimated from the errors in $\alpha$ ($\pm 0.16$, Kodaira and Watanabe 1988) and $i$ (Tab. 4). The second prescription is that of RC3, where $A(0) = 0.12$ and $\alpha = 0.8$ for NGC 6845 A and $A(0) = 0.1$ and $\alpha = 0.7$ for galaxies B, C and D. In this case we obtained $(M/L)_2 = 66.4 \pm 2.0$. Rose and Graham (1979) estimated M/L in the range 28—49, also depending on the source for Galactic and internal extinction corrections. Our $(M/L)_1$ is well inside their range of values, while $(M/L)_2$ is higher than their highest M/L ratio.

Although large, the difference between $(M/L)_1$ and $(M/L)_2$ points to a very similar total mass of the system $(1.0 \pm 0.2 \times 10^{13} M_\odot$ and $8.7 \pm 0.2 \times 10^{12} M_\odot$ respectively). The luminous mass of the system cannot account for more than $\approx 1.6 \times 10^{12} M_\odot$ (scaling the mass of the galaxies by their luminosities with respect to the mass and luminosity of NGC 6845 A), indicating that the group’s dark matter amounts to approximately 5 times higher than its luminous mass. The whole system contains almost 9 times more dark matter than what was thought to be associated with the halo of NGC 6845 A, as derived in the previous Section from HI kinematics.

4. Scenarios for the collision

Strong, well developed tidal bridges and tails are characteristic of galaxy encounters in which the disk of the perturbed galaxy and the orbit of the perturber rotate in the same sense, i.e., a prograde orbit, and the angle between the main galaxy disk and the orbital plane is small (e.g. Toomre and Toomre 1972; Negroponte and White 1983; Howard, et al. 1993). In prograde encounters, tidal arms curve in a sense opposite to the disk rotation: they are trailing. Consequently, we can infer that NGC 6845 A disk rotates counterclockwise (Sec. 3.4.1) and its SE side is preceding, indicating that the tidal bridge side is the near one.

Graham and Rubin (1973) already noted as curious that due to the relative position and radial velocities of galaxies A and B, any simple geometry would indicate that the B orbit is retrograde. However, as mentioned by these authors, the case might be similar to that of M 51/NGC 5195, for which Toomre and Toomre (1972) have found it possible to obtain a direct sense of rotation if the orbital eccentricity of NGC 5195 is large and if the orbit is highly inclined to the plane of M 51. From this point of view, galaxy C would be a good candidate for the strong interaction. Nevertheless, this galaxy presents itself as a symmetric disk up to faint brightness levels. Modern numerical simulations of similar disk encounters (e.g. Barnes 1992), shows that a collision between two large disks, like those of NGC 6845 A and C, close enough as to produce NGC 6845 A tidal bridge, would necessarily strongly distort NGC 6845 C disk as well.

In order to understand the dynamical evolution of this group, two of us (Rodrigues and Dottori 1999, in preparation), are developing extensive numerical simulations with the TreeSPH code (Hernquist and Katz 1989) in a CRAY T94 computer (CESUP–UFRGS). From this work we advance some preliminary results. In Figs. 10 and 11, we shows simulations of A with C and A with B collisions. Galaxy models were constructed following the general prescription of Kuijken and Dubinski (1995). Galaxy A model is such that its rotation curve presents a circular velocity of $300 \text{ km s}^{-1}$ at 6 kpc, and is approximately flat up to the cutoff radius (20 kpc). 10% of the disk mass is composed of gas particles, whose density profile is more extended than that of the stellar disk. For galaxy C we adopted the same model of A, but without gas, since this galaxy do not present HI or emission lines in its optical spectrum. A and C galaxy models consist of 6000 particles with a mass of $3.5 \times 10^{11} M_\odot$ per galaxy. Galaxy B is represented by a point mass of 1/4 of model A mass.
Fig. 10 shows the evolution of the encounter of models A and C, which approach along a parabolic orbit with a perigalactic distance \( q = 12 \text{kpc} \). The first row shows the time evolution of the stellar component, while the second row shows the same for the gas component. For easy of comparison between simulation and observations we used a coordinate system in which the z-axis corresponds to the line-of-sight (with positive values towards the observer), the x-axis is the E-W direction (positive to the West) and the y-axis is the N-S direction (positive to the North). In this system, the orbit of C around A has its pericenter in the direction of the vector \((-3, -10, 10)\), and the orbital plane is defined by the orbital spin vector, parallel to \((10, 3, 6)\). We identify the third frame of Fig. 11 (104 Myr after the perigalacticum) as the more similar to the system present stage. A striking result in favor of this scenario is the presence of a stellar condensation similar to that observed to the right of galaxy C NW extreme. C model SE extreme bend to the E, which is also observed to the faintest brightness levels in galaxy C (Fig. 1). The simulation also clearly shows that this collision produces a strong tidal feature similar to the NGC 6845 A tidal bridge with a condensation near its extreme that resembles H\(_{\text{II}}\) regions 4 and 5, but nothing as large as galaxy B is produced out of this encounter, so the position of galaxy B at the tidal bridge extreme would be a projection within this scenario. Against this scenario the simulation shows that about 10\% of the gas originally belonging to galaxy A would be captured by galaxy C, which is neither observed as H\(_{\text{II}}\) nor as H\(_{\text{I}}\). The simulation also shows that stars stripped out from A should form a stellar feature perpendicular to C disk, also not detected in the optical images, which present a high degree of symmetry to intermediate brightness levels.

Fig. 11 shows the encounter of model A with the point mass B, under a prograde hyperbolic orbit with eccentricity \( e = 2 \) and perigalactic distance \( q = 8 \text{kpc} \). The pericenter is in the direction \((20, -8, -10)\) and its orbital spin vector is parallel to \((8, 20, 0)\). The third frame (145 Myr after the perigalacticum, shown in the second frame) shows the best match of the model to the system present stage. In this frame galaxy B is receding with respect to A at \(300 \text{km s}^{-1}\). The more striking feature of this simulation is the morphology of the tidal bridge, which is straight and narrow and shows condensations of gas and stars at its base and middle part, resembling the observed tidal bridge morphology. Also the tidal tail is diffuse, as in the real situation. Against this scenario the simulation shows that the tidal tail points in a direction different from the observed one and does not bifurcate.

In spite of both scenarios pros and cons, the collision of A and B seems to be more appropriate to explain the tidal bridge structure. Although some features associated to galaxy C can be regarded as tidally produced, it cannot be ignored the lack of other important features that C should show if it were the main perturber. Perhaps a three-body interaction, with B producing the tidal bridge would be more suitable to explain the richness of features observed in this group.

5. **Concluding remarks**

The system NGC 6845 is a compact group in which NGC 6845 A presents a strong tidal bridge, signature of a close collision.

We present the first atomic Hydrogen observation of NGC 6845, obtaining an H\(_{\text{I}}\) content 5 times higher than in the case of the Milky Way. The H\(_{\text{I}}\) distribution can be separated into two components, one related to NGC 6845 A, sporting well developed tidal features and the second one, with velocity similar to that of NGC 6845 B. Components C and D do not present H\(_{\text{I}}\), up to our detection limit. This fact set constrains to galaxy C being the main perturber of A, since, as shown by numerical simulations, in these case gas originally belonging to A should be transferred to C.

NGC 6845 A optical rotation curve is asymmetric, with an uncommonly high maximum circular velocity, especially to the SW side. Satoh model fitting to the rotation curve indicates the presence of a dominant disk and a small to intermediate bulge, in agreement with the morphological classification of this galaxy. The derived mass is \(M_{\text{Satoh}} = 4.4(\pm 1.2) \times 10^{11} \text{M}_\odot\). The (B-I) color map indicate the presence of dust in front of the SW side of the bar, pointing to a trailing bar.

The (B-I) color map also shows that the bridge is bluer than NGC 6845 A inner disk. H\(_{\text{II}}\) regions brighter than those of the Antennae and NGC 7252 tidal tails have formed at the tip and
at the base of the tidal bridge. Three H\textsc{ii} regions midway along the tidal bridge are brighter than NGC 3603, the brightest one known in our galaxy. The kinematics of H\textsc{ii} regions 4 and 5 indicates that they are more likely connected to the tidal bridge than to NGC 6845 B, as their projected position may suggest. They present luminosities similar to that of 30 Doradus. A simple model for the kinematics of the tip of the bridge as well as numerical simulations indicate that star formation is occurring along this structure one hundred million years or more after the perturber closest approach.

The group kinematics calls for dark matter within the system at about 5 times its luminous mass. The group amount of dark matter would be 9 times higher than the halo mass of the NGC 6845 A, provided that the H\textsc{i} is in dynamical equilibrium inside the galaxy; this in turn would be three times higher than the galaxy kinematical mass derived from the optical rotation curve.

Since abundant signs of interactions are present in galaxy B, and to a less extent in C, we appealed to N-body simulations in order to disentangle which of the galaxies, B or C, would be the A main perturber. Both scenarios for the tidal disruption of galaxy A present pros and cons, but the bridge, which is the most conspicuous tidal feature of this galaxy, seems to be better reproduced by the simulation of the encounter of galaxies A and B. The fact that neither H\textsc{i} nor H\textsc{ii}, that should have been stripped out from galaxy A, are detected in galaxy C reinforce this scenario. Perhaps a three body interaction would be a more appropriate scenario to explain the group dynamical evolution, but it is difficult to model due to the large number of degrees of freedom involved such a collision.

We are grateful to Dr. Lars Hernquist, who kindly made available the TreeSPH code, to Mr. Ruben Diaz, who carried out the observations at Bosque Alegre and to Dr. Leo Girardi, who kindly provided his evolutionary synthesis models. The authors gratefully acknowledge the NRAO for allocating observing time and for support. We also thank the staff of CASLEO and Bosque Alegre. Numerical calculations were done at the CESUP-UFRGS national supercomputing center. This work was supported in part by the Brazilian institutions CNPq and FINEP.

|          | ±0.02 | ±0.04     | ±0.08     | ±0.18     | ±0.03  |          |            |            |          |            |            |           |           |            |

**Note.**—Col. (1): NGC 6845 group individual galaxy names. Col. (2): apparent blue magnitudes. Cols. (3), (4) and (5): colors. Col. (6): corrected inclination angle (see Sec. 3.4.4). Col. (7): corrections to apparent B magnitude for Galactic extinction (Burstein and Heiles 1984). Cols. (8) and (9): internal extinction corrections to face-on magnitudes, following Rubin et al. (1982) and RC3, respectively (see Sec. 3.4.4). Cols. (10) and (11): absolute blue magnitudes with corrections for internal absorption given by Δm_B(1) and Δm_B(2), respectively. We used the mean Galactocentric velocity of the group members as distance indicator. Cols. (12) and (13): absolute blue luminosity (erg s⁻¹) as taken from cols. (10) and (11), respectively (H₀ = 75 km s⁻¹ Mpc⁻¹).
Table 5
Integrated V magnitudes and colors for the condensations described in the text (see also Figure 3).

| Region | V       | (B-V)    | (V-R)   | (V-I)   | Age ($10^6$ yr) | Mass ($10^4 M_\odot$) |
|--------|---------|----------|---------|---------|----------------|------------------------|
| 1      | 16.38±0.02 | 0.17±0.04 | 0.06±0.09 | 0.27±0.11 | 6.9 ± 1.0 | 21 ± 5                |
| 2      | 16.43±0.04 | 0.15±0.08 | -0.02±0.12 | 0.12±0.22 | 6.3 ± 1.0 | 20 ± 5                |
| 3      | 16.45±0.01 | 0.20±0.02 | 0.00±0.12 | 0.15±0.13 | 6.5 ± 1.0 | 19 ± 5                |
| 4      | 16.03±0.02 | 0.28±0.03 | -0.05±0.08 | -0.30±0.16 | 6.6 ± 1.0 | 28 ± 5                |
| 5      | 16.18±0.02 | 0.26±0.03 | 0.05±0.06 | bn -0.28±0.12 | 6.6 ± 1.0 | 25 ± 5                |
| 6      | 18.52±0.06 | 0.27±0.09 | 0.11±0.19 | 0.50±0.43 | 8.0 ± 1.0 | 1.3 ± 5                |
| 7      | 14.57±0.01 | 0.26±0.02 | -0.13±0.05 | -0.48±0.09 | 5.3 ± 1.0 | 51 ± 5                |
| 8      | 14.81±0.01 | -0.37±0.02 | -0.10±0.06 | -0.40±0.09 | < 3.0 ± 1.0 | 40 ± 5                |

Note.—All regions were measured through a 4′′ aperture. Magnitudes were corrected for Galactic extinction with the standard absorption law, adopting $A_B = 0.16$ (Burstein and Heiles 1984) and for internal absorption using Hα/Hβ = 4.3 (see Sec. 3.2).
| Region         | $L_{\text{H}_\alpha}$ (erg s$^{-1}$) | $\text{H}_\alpha$ / $\text{H} \beta$ | Slit dimension (arcsec) | Slit pos. | Vel. (km s$^{-1}$) |
|----------------|--------------------------------------|------------------------------------|-------------------------|-----------|-------------------|
| (1)            | 1                                    | 2.3 $\times$ 10$^{39}$             | 6(1) $\times$ 6        | 2         | 6272             |
| (2)            | 2                                    | 3.0 $\times$ 10$^{39}$             | 6(1) $\times$ 6        | 2         | 6361             |
| (3)            | 3                                    | 1.8 $\times$ 10$^{39}$             | 6(1) $\times$ 6        | 2         | 6455             |
| (4)            | 4                                    | 9.1 $\times$ 10$^{39}$             | 2.3 $\times$ 6         | 7.3;5     | 6314             |
| (5)            | 5                                    | 6.5 $\times$ 10$^{39}$             | 2.3 $\times$ 6         | 6         | 6201             |
| (6)            | 6                                    | ...                                | ...                     | ...       | ...              |
| (7)            | 7                                    | 2.2 $\times$ 10$^{40}$             | 2 $\times$ 6.2         | 4         | 6113             |
| (8)            | 8                                    | 8.7 $\times$ 10$^{39}$             | 2 $\times$ 6           | 4         | 6660             |
| NGC 6845 A     | 9                                    | 7.7 $\times$ 10$^{39}$             | 2 $\times$ 10          | 4         | 6399             |
| NGC 6845 B     | 10                                   | 1.1 $\times$ 10$^{40}$             | 2.3 $\times$ 8         | 6;7       | 6746             |

**Note.**—Col. (1): region label as in Table 5 and Fig. 3. Cols. (2) and (3): $\text{H}_\alpha$ luminosities and $\text{H}_\alpha$ / $\text{H} \beta$ ratios, respectively. Col. (4): slit dimensions. The numbers in parentheses on the slit dimension of regions 1, 2 and 3 correspond to the slit width of the spectrum used to measure velocities, while the values outside the parentheses is for the spectra used to measure flux. Col. (5): slit position, as in Table 3. In region 4, three slit positions were used: position 7 to measure $\text{H}_\alpha$ flux and radial velocity and positions 3 and 5 to measure $\text{H}_\alpha$-to-$\text{H} \beta$ ratio. Col. (6): heliocentric radial velocity of the region.
Fig. 1.— A 600 s R–band image of the group of galaxies NGC 6845 or Klemola 30. The contrast is chosen so as to emphasize low surface brightness levels. A very good photo of this group can be seen in Rose (1979) (1979).

Fig. 2.— (B-I) color map. 10 grey levels are shown, ranging from 0.5 (white) to 3.5 mag pix$^{-1}$ (black).

Fig. 3.— The same as Fig. 1, detaching bright condensations. The circles show the positions of the HII regions whose photometric and spectroscopic measurements are presented in Tables 5 and 6. Left hand panel: radial velocities of the galaxies A, B, C and D, as well as of some selected positions. Right hand panel: detail of the tidal bridge, showing HII regions 1, 2 and 3.

Fig. 4.— Composite image showing our optical spectra towards seven of the eight HII regions indicated in Table 5 and Fig. 3 The left panel shows the entire observed wavelength range whereas the right one shows the spectral region around Hα and [SII]$\lambda\lambda 6717,6731$.

Fig. 5.— Slit positions for the spectra of Table 3. Slit lengths are not in scale.

Fig. 6.— HI contour map superimposed to the R image of NGC 6845. Full lines: HI associated to NGC 6845 A, with count peak flux = $4.08 \times 10^3$ Jy/B * m/s. Ten equally spaced contour levels from $0.4 \times 10^3$ to $4.0 \times 10^3$ Jy/B * m/s are plotted. Dashed lines: HI associated to NGC 6845 B (mean velocity 6700 km s$^{-1}$, with count peak flux = $0.95 \times 10^3$ Jy/B * m/s. Contour levels are $0.4 \times 10^3$ and $0.8 \times 10^3$ Jy/B * m/s. Beam size is shown at the lower left corner.

Fig. 7.— Rotation curve of NGC 6845 A. Different symbols are used to distinguish between SW (filled circles) and NE (empty triangles) directions. The full line gives our best Satoh model fit to the observed data set ($\chi^2 = 48.5$ and RMS = 18.1; $a = 6.5 \pm 0.4$ and $b/a = 0.3 \pm 0.1$). Dashed lines give the upper and lower limits of the fitted curve within the observational errors.

Fig. 8.— HI velocity map superimposed to the R image of NGC 6845. Velocity levels are from 6350 to 6700 km s$^{-1}$ in intervals of 50 km s$^{-1}$.

Fig. 9.— NGC 6845 A HI position–velocity diagram, obtained by cutting the data cube along the galaxy major axis, coincident with the slit number 4 in Figure 5, the one used to obtain the optical rotation curve of NGC 6845 A (Fig. 7). X-axis corresponds to the cut projection on the declination direction. Contour levels are drawn at 0.30, 0.75, 1.0, and 1.5 Kelvin.

Fig. 10.— Evolution of the encounter of model galaxies A (with gas) and C (without gas), viewed in the “sky plane”. The top row shows only the stellar content, while the bottom row shows only gas particles. The frames measure 112 kpc on a side, and time is shown in the upper right.

Fig. 11.— Evolution of the encounter of galaxy model A and a point mass representing galaxy B, viewed in the “sky plane”. The top row shows the stellar content, while the bottom row shows the gas particles. The frames measure 112 kpc on a side, and time is shown in the upper right.
