We study properties of excited states of an array of weakly coupled quasi-two-dimensional Bose condensates by using the hydrodynamic theory. The spectrum of the axial excited states strongly depends on the coupling among the various discrete radial modes in a given symmetry. By including mode-coupling within a given symmetry, the complete excitation spectrum of axial quasiparticles with various discrete radial nodes are presented. A single parameter which determines the strength of the mode coupling is identified. The excitation spectrum in the zero angular momentum sector can be observed by using the Bragg scattering experiments.

I. INTRODUCTION

The experimental realization of optical lattices is stimulating new perspectives in the study of cold bosons. Optical lattices have enabled us to observe quantum phenomena such as number squeezing, collapses and revivals and the diffraction of matter waves. Apart from these examples, BEC in optical lattices are particularly promising physical systems to study the superfluid properties of Bose gases. The Bose-Hubbard model has been realized and the quantum phase transition from superfluid to a Mott insulator state was indeed observed experimentally. It was predicted that for deep optical lattices the condensate superflow can be lost not only by energetic instability but also by dynamical instability. The dynamic instability was verified by the experiments. In a seminal work by Kramer et al., they have found the mass renormalization in presence of the potential which decreases the value of the axial excitation frequencies. These discrete axial excitation frequencies are experimentally verified. There are several theoretical calculations have studied the MBBS only for monopole and lowest energy quadrupole modes without considering the coupling among the various modes with zero angular momentum. Martikainen and Stoof have calculated the spectrum of the phonon and the monopole modes by considering only the coupling between the phonon and the breathing modes. But it is noted that the sound mode is coupled not only with the breathing mode but also with other low energy modes having zero angular momentum. Similarly, the lowest energy quadrupole mode is also coupled with other low energy quadrupole modes. There is a lack of complete study on the MBBS in this system. For complete and correct description of MBBS we have to consider the couplings among all low energy modes in the same angular momentum sector. In our discretize hydrodynamic description, the couplings among all the modes in the same angular momentum sector are included naturally and we will see in the next section.

In this work we study the excitations in a stack of weakly coupled quasi-two-dimensional condensates. The multibranch Bogoliubov-Bloch spectrum of such system is presented by using the hydrodynamic theory. The MBBS strongly depends on the coupling between the inhomogeneous density in the radial plane and the density modulation along the symmetry axis. Note that one can study only the spectrum of sound, monopole and quadrupole modes without considering the mode coupling completely by using the time-dependent Gaus-
sian variational method. Our discretize hydrodynamic method presented in this paper goes beyond the time-dependent variational method. In principle, we can calculate all low energy spectrum by including the mode coupling in a given angular momentum sector as long as the excitation energies are less than the chemical potential. We find that the multibranch Bogoliubov-Bloch spectrum changes due to presence of the mode-coupling within a given angular momentum symmetry. Therefore, the mode-coupling should be taken into account while calculating the spectrum correctly.

This paper is organized as follows. In Sec.II, we consider an array of weakly coupled quasi-two-dimensional Bose condensates. Using the discretize hydrodynamic theory, we calculate the multibranch Bogoliubov-Bloch spectrum by including the mode coupling within a given symmetry. We give a brief summary and conclusions in Sec. III.

II. MBBS OF A NON-ROTATING ARRAY OF BOSE CONDENSATES

We assume that the bosonic atoms, at $T = 0$, are trapped by an external potential given by the sum of a harmonic trap and a stationary optical potential modulated along the $z$ axis. The Gross-Pitaevskii energy functional can be written as

$$E_0 = \int dV \psi^\dagger \left( \frac{\hbar^2}{2M} \nabla^2 + V_{ho}(r, z) \right) \psi + \frac{g}{2} |\psi(r, z)|^2 V_{op}(z) |\psi(r, z)|.$$  (1)

Here, $V_{ho}(r, z) = \frac{M}{2} (\omega_r^2 r^2 + \omega_z^2 z^2)$ is the harmonic trap potential and $V_{op}(z) = s E_r \sin^2(\theta z)$ is the optical potential where $E_r = \frac{h^2 q^2}{2 M}$ is the recoil energy, $s$ is the dimensionless parameter determining the laser intensity and $q$ is the wave vector of the laser beam. Also, $g = \frac{4 \pi a_s \hbar^2}{s}$ is the strength of the two-body interaction energy, where $a_s$ is the two-body scattering length. We also assumed that $\omega_r \gg \omega_z$ so that it makes a long cigar shaped trap. The minima of the optical potential are located at the points $z_j = j \pi / q = j d$, where $d = \pi / q$ is the lattice size along the $z$-axis. Around these minima, $V_{op}(z) \sim M / 2 \omega_z^2 (z - z_j)^2$, where the layer trap frequency is $\omega_z = \sqrt{s \hbar q^2 / M}$. In the usual experiments, the well trap frequency is larger than the axial harmonic frequency, $\omega_r \gg \omega_z$. Therefore, we can also ignore the harmonic potential along the $z$-axis since the deep optical lattice dominates over the harmonic potential along the $z$-axis.

The strong laser intensity will give rise to an array of several quasi-two-dimensional condensates. Because of the quantum tunneling, the overlap between the wave functions between two consecutive layers can be sufficient to ensure full coherence. If the tunneling is too small, the strong phase fluctuations will destroy the coherence and lead to a new quantum state, namely Mott insulator state.

In the presence of coherence among the layers it is natural to take the ansatz for the wave function as

$$\psi(x, y, z) = \sum_j \psi_j(x, y) f(z - z_j).$$  (2)

Here, $\psi_j(x, y)$ is the wave function of the two-dimensional condensate at the site $j$ and $f(z - z_j)$ is a localized function at $j$-th site. The localized function can be written as

$$f(z - z_j) = \left( \frac{M \omega_x}{2 \pi \hbar} \right)^{1/4} e^{-\frac{M \omega_x}{2 \pi \hbar} (z - z_j)^2}.$$  (3)

Substituting the above ansatz into the energy functional and considering only the nearest-neighbor interactions, one can get the following energy functional:

$$E_0 = \sum_j \int dxdy \left[ \frac{\hbar^2}{2M} \psi_j^\dagger \nabla^2 \psi_j + V_{ho} |\psi_j|^2 \right] + \frac{g_{2D}}{2} \sum_j \int dxdy \psi_j^\dagger \psi_j \nabla^2 \psi_j - \frac{J}{4} \sum_{j, \delta = \pm 1} \int dxdy [\psi_{j+\delta}^\dagger \psi_{j+\delta} + \psi_j^\dagger \psi_j].$$  (4)

Here, $J$ is the strength of the Josephson coupling between adjacent layers which is given as

$$J = - \int dz f(z) \left[ \frac{\hbar^2}{2M} \nabla^2 + V_{op}(z) \right] f(z + d) \sim \hbar \omega_r \left( \frac{\pi a_s}{\sqrt{2} a_{op}} \right)^2 (\pi^2 - 4) s e^{-\frac{\pi^2}{4}},$$  (5)

where $a_s = \left( \frac{\hbar}{M \omega_x} \right)^{1/2}$. Also, the strength of the effective on-site interaction energy is $g_{2D} = g \int dz |f_0(z)|^4 = 4 \sqrt{\pi} \hbar \mu_{2D} (\frac{\pi}{4})$, where $a_s = \sqrt{\hbar / M \omega_x}$. Eq. (6) shows that each layer $j$ is coupled with the nearest-neighbor layers $j = \pm 1$ through the tunneling energy $J$. The axial dimension appears through the Josephson coupling between two adjacent layers. The Hamiltonian corresponding to the above energy functional is similar to an effective 1D Bose-Hubbard Hamiltonian in which each lattice site is replaced by a layer with radial confinement.

The Heisenberg equation of motion for the bosonic order parameter is

$$i \hbar \dot{\psi}_j = \left[ - \frac{\hbar^2}{2M} \nabla^2 + V_{ho} + g_{2D} \psi_j^\dagger \psi_j \right] \psi_j - J (\psi_{j+1} + \psi_{j-1}).$$  (6)

Using the phase-density representation of the bosonic field operator as $\psi_j = \sqrt{\bar{n}_j} e^{i \theta_j}$ and neglecting the quantum pressure term, one can get the following equations of motion for the density and phase:

$$\dot{n}_j = - \frac{\hbar}{M} \nabla_r \cdot (n_j \nabla_r \theta_j) + \frac{2J}{\hbar} \left( \sqrt{n_j} n_{j-1} \sin(\theta_j - \theta_{j-1}) - \sqrt{n_j} n_{j+1} \sin(\theta_{j+1} - \theta_j) \right),$$  (7)
\[ \hbar \dot{\theta}_j = -\frac{\hbar^2}{2M} (\nabla_r \theta_j)^2 + J \left[ \sqrt{\frac{n_{j+1}}{n_j}} \cos(\theta_{j+1} - \theta_j) + \sqrt{\frac{n_{j-1}}{n_j}} \cos(\theta_j - \theta_{j-1}) \right] - V_{\text{ho}} - g_{2D} n_j. \]  

(8)

Here, \( \cdot \) represents the time derivative. In equilibrium, the condensate density at each layer is \( n_0(r) = \frac{\mu - V_{\text{ho}}(r)}{g_{2D}} \), where we have neglected the effect of the tunneling energy \( J \) since it is very small in the deep optical lattice regime.

Also, \( \mu_0 = \hbar \omega_r \sqrt{\frac{8}{\pi} \frac{2\omega}{\omega_s}} \) is the chemical potential at each layer, where \( N \) is the number of atoms at each layer. In this system, we have two energy scales: the chemical potential of each layer \( \mu_0 \sim s^{1/8} \) which is associated with the radial plane and the tunneling energy \( J \sim \omega_r^{-\frac{1}{2}} \) which is associated with the density modulation along the \( z \)-axis. The strength of the chemical potential can be enhanced by increasing the lattice depth or by increasing the number of atoms. The tunneling energy \( J \) decreases with the increasing of the lattice depth.

We linearize the hydrodynamic equations around the equilibrium state, as \( n_j = n_0 + \delta n_j \) and \( \theta_j = \delta \theta_j \). The equations of motion for the density and phase fluctuation becomes

\[ \delta \dot{n}_j = -\frac{\hbar}{M} \nabla_r \cdot [n_0(r) \nabla_r \delta \theta_j] + 2J \frac{\hbar}{n_0(r)} [2\delta \theta_j - \delta \theta_{j-1} - \delta \theta_{j+1}] \]  

(9)

and

\[ \hbar \delta \dot{\theta}_j = -g_{2D} \delta n_j - \frac{J}{2n_0(r)} [2\delta n_j - \delta n_{j-1} - \delta n_{j+1}] \]  

(10)

Note that the second term of the right hand side of Eq. (10) is proportional to the small parameter \( J \) and inversely proportional to the large parameter \( n_0(r = 0) = \mu_0 / g_{2D} \). Therefore, we can neglect the term which is proportional to the \( J / 2n_0(r) \). After some algebra, we get second order equation of motion for the density fluctuation as

\[ \delta \ddot{n}_j = \frac{g_{2D}}{M} \nabla_r \cdot (n_0(r) \nabla_r \delta n_j) - \frac{2J g_{2D}}{\hbar^2} n_0(r) [2\delta n_j - \delta n_{j-1} - \delta n_{j+1}] \]  

(11)

The above equation tells us that the density fluctuation at each layer \( j \) is coupled with the nearest-neighbor layers \( j \pm 1 \). We seek the normal mode solutions of the density fluctuations at layer \( j \) in the following form:

\[ \delta n_j = \delta n(r) e^{i (jkd - \omega_l(k))t}. \]  

(12)

Here, \( k \) is Bloch wave vector (quasi-momentum) of the excitations. The Bloch wave vector \( p \) which is associated with the velocity of the condensate in the optical lattice is set to zero.

Substituting the above equation into Eq. (11), we get

\[ -\omega_l^2(k) \delta n = \frac{g_{2D}}{M} \nabla_r \cdot (n_0(r) \nabla_r \delta n) - \frac{8J g_{2D}}{\hbar^2} n_0(r) \sin^2(kd/2) \delta n, \]  

(13)

where \( l \) is a set of two quantum numbers: radial quantum number, \( n_r \) and the angular quantum number, \( m \). The parameter \( J \mu \) in front of the \( \sin^2(kd) \) term determines the strength of the coupling between the inhomogeneous density in the radial plane and the density modulation along the \( z \)-axis.

For \( k = 0 \), the solutions are known exactly and analytically [25]. The energy spectrum and the normalized eigen functions, respectively, are given as, \( \omega_l^2 = \omega_r^2 [m^2 + 2n_r(n_r + |m| + 1)] \)

\[ \delta n(r, \phi) = \frac{1 + 2n_r + |m|}{2 |m|} \left( \frac{\pi R_0^2}{|m|} \right)^{1/2} P_n^{(|m|,0)}(1 - 2r^2)e^{im\phi}. \]  

(14)

Here, \( P_n^{(a,b)}(x) \) is the Jacobi polynomial of order \( n \) and \( \phi \) is the polar angle. The radius of each condensate layer \( R_0 = 2\mu_0 / M \omega_r^2 \) and \( R = r / R_0 \) is the dimensionless variable.

The solution of Eq. (13) can be obtained for arbitrary value of \( k \) by numerical diagonalization. For \( k \neq 0 \), we can expand the density fluctuations as

\[ \delta n(r) = \sum_l b_L \delta n_L (r, \phi). \]  

(15)

Substituting the above expansion into Eq. (13), we obtain

\[ 0 = \omega_l^2 - [m^2 + 2n_r(n_r + |m| + 1)] \]  

\[ - B_0 \sin^2(kd/2) b_l + B_0 \sin^2(kd/2) \sum_{l'} M_{ll'} b_{l'} \]  

(16)

where \( \omega_l = \omega_l / \omega_r \) and the dimensionless parameter \( B_0 \) is defined as

\[ B_0 = \frac{8J \mu_0}{\hbar^2 \omega_r^2}. \]  

(17)

The matrix element \( M_{ll'} \) is given by

\[ M_{ll'} = \frac{(1 + 2n_r + |m|)}{\pi} \int d^2r r^2 \sin^2(|m| + |m'|) e^{i(m - m')\phi} \]  

\[ \times P_n^{(|m|,0)}(1 - 2r^2) P_{n_r}^{(|m|,0)}(1 - 2r^2). \]  

(18)

The above eigenvalue problem is block diagonal with no overlap between the subspaces of different angular momentum, so that the solutions to Eq. (13) can be obtained separately in each angular momentum subspace. We can obtain all low energy multibranch Bogoliubov-Bloch spectrum from Eq. (10) which is our main result. Equations (10) and (18) show that the spectrum depends on average over the radial coordinate and the
coupling among the modes within a given angular momentum symmetry for any finite value of $k$. Particularly, the couplings among all other modes are important for large values of $kd$ and $B_0$. It is interesting to note that the curvature of a mode spectrum depends on a single parameter $B_0$ which is defined in Eq. (17). The parameter $B_0$ can remain unchanged by changing values of the $J$ and $\mu_0$ in a various combination. Therefore, the curvatures of the spectrum of a given mode for various combinations of $J$ and $\mu_0$ with fixed $B_0$ are the same.

Before presenting the exact numerical results, we make some approximation for a quantitative discussions. If we neglect the couplings among all other modes in the $m = 0$ sector by setting $l = (n_r, 0)$ in Eqs. (16) and (18), one can easily get following spectrum:

$$\tilde{\omega}_{n_r}^2 = 2n_r(n_r + 1) + (1 - M_{n_r,n_r})B_0 \sin^2(kd/2).$$  (19)

The above equation can also be obtained by using first-order perturbation theory to Eq. (13). In the limit of long wavelength, the $n_r = 0$ mode is phonon-like with a sound velocity $c_0 = \sqrt{\frac{k_d^2}{2M^*}}$, where $M^* = \frac{\hbar^2}{2\omega_r}$, is the effective mass of the atoms in the optical potential. This sound velocity exactly matches with the result obtained in Ref. [14] and is similar to the result obtained without optical potential [20]. This sound velocity is smaller by a factor of $\sqrt{2}$ with respect to the sound velocity obtained previously [16, 17, 18, 19] for quasi-1D Bose gas placed in an optical potential. This is due to the effect of the group velocity along the $z$ direction deviates from its long-wavelength limit when $kd \sim \pi$. The mode coupling induced by the $\sin^2(kd)$ perturbation in Eq. (11) becomes more significant with increasing $k$ and has the effect of lowering the sound speed. This coupling is associated with the interplay of the density modulation along the $z$ direction and the strong inhomogeneity of the equilibrium density in the radial direction in each plane. The effective masses are negative when $kd > \pi$.

The coupling between the transverse quadrupole modes ($m = \pm 2$) and the modes in the $m \neq \pm 2$ sector does not exist since these modes are orthogonal to each other as it can be seen from Eq. (18). However, the lowest energy quadrupole spectrum ($n_r = 0, m = \pm 2$) strongly depends on other low-energy quadrupole modes with various discrete radial nodes ($n_r \neq 0, m = \pm 2$). We neglect the couplings among all other modes in the $m = \pm 2$ sector by setting $l = (n_r, 2)$ in Eqs. (16) and (18), then one can easily get following spectrum:

$$\tilde{\omega}_{n_r}^2 = 2 + 2n_r(n_r + 3) + (1 - M_{n_r,2n_r,2})B_0 \sin^2(kd/2).$$  (20)

In Fig. 1, we show few low-energy multibranch Bogoliubov-Bloch spectrum in the $m = 0$ sector as a function of $kd$ by solving the matrix Eq. (16).

![Figure 1: Plots of the low-energy Bogoliubov-Bloch modes in the $m = 0$ sector. Here, $J = 0.1\hbar\omega_r$ and $\mu_0 = 50\hbar\omega_r$. Solid and Dashed lines are obtained from Eq. (16) and Eq. (18), respectively.](image)

The lowest branch corresponds to the Bogoliubov-Bloch axial mode with no radial nodes. This mode has the usual form like $\omega_r = c_s k$ at low momenta, where $c_s$ is the real sound velocity. Note that $c_s \lesssim c_0$ which implies that the dispersion relations are modified due to the coupling among all other modes. The changes in the spectrum is clearly visible in the central part of the Brillouin zone. This is due to the fact that the mode coupling is strong enough in the central part of the Brillouin zone due to the particular nature of the $k$-dependent part (see Eq. (15)). The second branch corresponds to one radial node and starts at $2\omega_r$ for $k = 0$. The breathing mode has the free-particle dispersion relation and it can be written in terms of the effective mass ($m_0^*$) of this mode as $\omega_0(k) = 2\omega_r + \frac{\hbar^2}{2m_0^*}$. Fig. 1 shows that the mode-coupling does not affect on the breathing mode spectrum appreciably. The third and fourth lowest energy modes are also given in Fig. 1. These modes are also changed in the central part of the Brillouin zone due to the mode-coupling. One could see from Fig. 1 that the effective masses of each modes are different. The group velocity along the $z$ direction deviates from its long-wavelength limit when $kd \sim \pi$. The mode coupling induced by the $\sin^2(kd)$ perturbation in Eq. (11) becomes more significant with increasing $k$ and has the effect of lowering the sound speed. This coupling is associated with the interplay of the density modulation along the $z$ direction and the strong inhomogeneity of the equilibrium density in the radial direction in each plane. The effective masses are negative when $kd > \pi$.

The coupling between the transverse quadrupole modes ($m = \pm 2$) and the modes in the $m \neq \pm 2$ sector does not exist since these modes are orthogonal to each other as it can be seen from Eq. (18). However, the lowest energy quadrupole spectrum ($n_r = 0, m = \pm 2$) strongly depends on other low-energy quadrupole modes with various discrete radial nodes ($n_r \neq 0, m = \pm 2$). We neglect the couplings among all other modes in the $m = \pm 2$ sector by setting $l = (n_r, 2)$ in Eqs. (16) and (18), then one can easily get following spectrum:

$$\tilde{\omega}_{n_r}^2 = 2 + 2n_r(n_r + 3) + (1 - M_{n_r,2n_r,2})B_0 \sin^2(kd/2).$$  (20)

In Fig. 2, we present first two low-energy MBBS for quadrupole modes. Fig. 2 clearly shows that the mode-coupling reduces the spectrum also for the quadrupole modes in the central part of the Brillouin zone.

In Ref. [23], the spectrum for the breathing and the lowest energy quadrupole modes are obtained analytically within the Gaussian variational analysis. The mode coupling was not considered in this variational analysis [23]. In Fig. 3, we compare the spectrum of the breathing and lowest energy quadrupole modes obtained from Eq. (16) with those of obtained in Ref. [23]. It is clear from Fig. 3 that the mode-coupling reduces the spectrum strongly and it should be taken into account for calculating the spectrum correctly.
FIG. 2: Plots of the low-energy Bogoliubov-Bloch modes in the \( m = \pm 2 \) sector. Here, \( J = 0.1\hbar \omega_r \) and \( \mu_0 = 50\hbar \omega_r \). Solid and Dashed lines are obtained from Eqs. (16) and (20), respectively.

FIG. 3: Plots of the spectrum of breathing and lowest energy quadrupole modes. Here, \( J = 0.1\hbar \omega_r \) and \( \mu_0 = 50\hbar \omega_r \). Solid and Dashed lines are obtained from Eq. (16) and Ref. [23], respectively.

III. SUMMARY AND CONCLUSIONS

In this work, we have studied excitation energies of the axial quasiparticles with various discrete radial nodes of an array of weakly coupled quasi-two dimensional Bose condensates. Our discretize hydrodynamic description enables us to produce correctly all low-energy MBBS by including the mode couplings among different modes within the same angular momentum sector. We found that the mode-coupling strongly changes the spectrum. Therefore, it should be taken into account to calculate such spectrum correctly. The mode coupling is strong enough in the central part of the Brillouin zone. The single parameter \( B_0 \), defined in Eq. (17), is identified which is always associated with the \( k \)-dependent part and it scales with the product of two energy scales of this system, namely \( J \) and \( \mu_0 \). The parameter \( B_0 \) is a good measure for determination of the effect of the optical lattices on the spectrum. Particularly, the spectrum for the phonon and breathing modes can be observed in a Bragg scattering experiments as discussed below. The MBBS can be observed in the Bragg scattering experiments as the MBS was observed in Ref. [22]. Due to the axial symmetry, the modes having only zero angular momentum can be excited in the Bragg scattering experiments. In the Bragg spectroscopy, the condensate is excited by an external moving optical potential \( V = V_B(t) \cos(kz - \omega t) \), where \( V_B(t) \) is the intensity of the Bragg pulses. This optical potential is created by using two Bragg pulses with approximately parallel polarization, separated by an angle \( \theta \). The pulses have a frequency difference \( \omega \) determined by two acousto-optic modulators. The wave-vector \( k \) is adjusted to be along the \( z \)-axis. Both the values of \( k \) and \( \omega \) can be tuned by changing the angle between two beams and varying their frequency difference. For small values of \( k \) the system is excited in the phonon regime and the response is detected by measuring the net momentum, \( P_z(\omega,k) \), imparted to the system by the Bragg pulses. The multibranch Bogoliubov spectrum is obtained by observing the locations of the peaks in \( P_z(\omega,k) \) for various values of \( k \). The frequency \( \omega \) must be comparable to radial trap frequency \( \omega_r \) in order to excite the breathing and other modes. The duration of the Bragg pulses must be larger than the radial trapping period, \( T_B > 2\pi/\omega_r \) in order to have large populations of the radial quasiparticle states.
