Micron scale silicon nitride (SiN$_x$) microdisk optical resonators are demonstrated with $Q = 3.6 \times 10^6$ and an effective mode volume of $15(\lambda/n)^3$ at near-visible wavelengths. A hydrofluoric acid wet etch provides sensitive tuning of the microdisk resonances, and robust mounting of a fiber taper provides efficient fiber optic coupling to the microdisks while allowing unfettered optical access for laser cooling and trapping of atoms. Measurements indicate that cesium adsorption on the SiN$_x$ surfaces significantly red-detunes the microdisk resonances. A technique for parallel integration of multiple (10) microdisks with a single fiber taper is also demonstrated.

Atom chip technology$^{[1, 2]}$ has rapidly evolved over the last decade as a valuable tool in experiments involving the cooling, trapping, and transport of ultra-cold neutral atom clouds. During the same period there has been significant advancement in microphotonic systems$^{[3, 4]}$ for the guiding and trapping of light in small volumes, with demonstrations of photonic crystal nanocavities capable of efficiently trapping light within a cubic wavelength$^{[4]}$ and chip-based silica microtoroid resonators$^{[5]}$ with photon lifetimes well over $10^8$ optical cycles. Poised to significantly benefit from these developments is the field of cavity quantum electrodynamics (cavity QED)$^{[6]$, in which strong interactions of atoms with light inside a resonant cavity can be used to aid in quantum information processing and in the communication and distribution of quantum information within a quantum network$^{[7, 8]}$. Integration of atomic and microphotonic chips$^{[8, 9, 10]}$ offers several advancements to the current state-of-the-art Fabry-Perot cavity QED systems$^{[11]}$, most notably a scalable platform for locally controlling multiple quantum bits and an increased bandwidth of operation. In this Letter we demonstrate the suitability of silicon nitride (SiN$_x$) for high-$Q$, small mode volume microcavities resonant at near-visible wavelengths necessary for cavity QED with alkali atoms, and describe a robust mounting technique which enables the integration of a permanently fiber-coupled microdisk resonator with a magnetostatic atom chip.

In addition to the obvious benefits of the fabrication maturity of the silicon(Si)-silicon oxide(SiO$_x$) materials system, recent work has shown that high quality atom chips can be created from thermally evaporated gold metal wires on thin oxide coated Si wafers$^{[12]}$. Integration with a SiN$_x$ optical layer provides a path towards a monolithic atom-cavity chip with integrated atomic and photonic functionality. Indeed, owing to its moderately high index of refraction ($n \approx 2.0-2.5$) and large transparency window ($6 \mu m > \lambda > 300\, nm$)$^{[13, 14]}$, SiN$_x$ is an excellent material for the on-chip guiding and localization of light. The high refractive index of SiN$_x$ makes possible the creation of a variety of wavelength scale microcavity geometries such as whispering-gallery$^{[15, 16]}$ or planar photonic crystal structures$^{[17]}$, with a small intrinsic radiation loss. Combined with a lower index SiO$_x$ cladding, waveguiding in a SiN$_x$ layer can be used to distribute light within a planar microphotonic circuit suitable for high-density integration. The low absorption loss across the visible and near-IR wavelengths, on the other hand, allows SiN$_x$ to be used with a diverse set of atomic and atomic-like (colloidal quantum dots, color centers, etc.) species. Beyond the particular focus of this work on cavity QED experiments with cold alkali atoms, high-$Q$ SiN$_x$ microcavities are also well suited to experiments in-
volving moderate refractive index environments, such as sensiti-
vive detection of analytes contained in a fluid solution [18] or absorbed into a low index polymer cladding [19]. The \( \text{SiN}_x \) microdisk resonators in this work were fabricated from a commercially available \( \text{Si} \) wafer with a 250 nm thick stoichiometric \( \text{SiN}_x \) \((n = 2.0) \) layer grown on the surface by low pressure chemical vapor deposition (LPCVD). Fabrication of the microdisk resonators involved several steps, beginning with the creation of a highly circular electron beam resist etch mask through electron beam lithography and a resist reflow [20]. A \( \text{C}_6\text{F}_{13}/\text{SF}_6 \) plasma dry etch was optimized to transfer the resist etch mask into the \( \text{SiN}_x \) layer as smoothly as possible. This was followed by a potassium hydroxide wet etch to selectively remove the underlying (100) \( \text{Si} \) substrate until the \( \text{SiN}_x \) microdisks were supported by a small micron diameter silicon pillar. A final cleaning step to remove organic materials from the disk surface was performed using a \( \text{H}_2\text{SO}_4/\text{H}_2\text{O}_2 \) wet etch. A SEM image of a fully processed microdisk is shown in Fig 1(a,b).

The optical modes of the fabricated microdisks were efficiently excited via an optical fiber taper waveguide [21, 22]. A swept wavelength source covering the 840-856 nm wavelength band was coupled into the fiber taper waveguide and used to measure the fine transmission spectra of the microdisk resonators at wavelengths close to the D2 transition of cesium (Cs). Details of the fiber taper measurement set-up can be found in Ref. [22]. Figure 2(a) shows a typical measured wavelength scan of the lowest radial order \((p = 1) \) TE-like mode of a 9 \( \mu \text{m} \) diameter \( \text{SiN}_x \) microdisk. The resonance has an intrinsic linewidth of 0.26 pm, corresponding to a quality factor \( Q = 3.6 \times 10^9 \). The doublet structure in the transmission spectra is due to mode-coupling between the clockwise and counter-clockwise modes of the disk due to surface roughness induced backscattering [23]. In addition to this high-Q mode, the 9 \( \mu \text{m} \) microdisks also support a lower \( Q \) higher-order radial mode in the 850 nm wavelength band. The free spectral range between modes of the same radial order but different azimuthal number \((m) \) was measured to be 5.44 THz (13 nm), resulting in a finesse of \( f' = 5 \times 10^4 \) for the \( p = 1 \), TE-like modes. Tests of less surface sensitive larger diameter microdisks showed reduced doublet splitting but no reduction in linewidth, indicating that \( Q \) is most likely limited by material absorption and not surface roughness [20]. This bodes well for utilizing these \( \text{SiN}_x \) microdisks at even shorter wavelengths, such as the 780 nm D2 transition of rubidium.

Finite-element method (FEM) simulations [24] (Fig. 1(c)) show that the effective optical mode volume, defined by \( V_{\text{eff}} = \int n^2(r)E^2(r)dr/|n^2(r)E^2(r)|_{\max} \), is as small as 15 \((\lambda/n)^3\) for the 9 \( \mu \text{m} \) diameter microdisks. The corresponding parameters of cavity QED, the Cs-photon coherent coupling rate \((g)\), photon field decay rate \((\kappa)\), and Cs transverse decay rate \((\gamma_L)\) are \([g, \kappa, \gamma_L]/2\pi = [2.4, 0.05, 0.003] \) GHz for an atom at the microdisk surface, indicating that these cavities are capable of operating well within the regime of strong coupling [6]. For an atom displaced 100 nm from the surface, \( g/2\pi \) drops to 0.9 GHz. FEM simulations show that for microdisks of diameter below 9 \( \mu \text{m} \) the intrinsic radiation \( Q \) drops rapidly below the 10\(^8\) level.

Using the above fabrication procedure the resonance wave-
length \((\lambda_o)\) of the microdisk modes could be positioned with an accuracy of \( \pm 0.5 \) nm. In order to finely tune \( \lambda_o \) into alignment with the D2 atomic Cs transition a series of timed etches in 20:1 diluted 49% HF solution was employed. By slowly etching the LPCVD \( \text{SiN}_x \) the resonance wavelength of the high-\( Q \) disk modes was shown to blue shift at a rate of 1.1 nm/min (Fig. 2(c)). With this technique the cavity resonance could be positioned with an accuracy of \( \pm 0.05 \) nm without degrading the \( Q \) factor (Fig. 2(b)). Further fine tuning can be accomplished by heating and cooling of the sample; a tempera-
ture dependence of \( d\lambda_o/dT \sim 0.012 \) nm/°C was measured for the \( p = 1 \), TE-like microdisk modes.

After initial device characterization and tuning of \( \lambda_o \), the fiber taper and microdisk chip were integrated with an atom chip consisting of a sapphire substrate with electropolished gold microwires underneath a top evaporated gold mirror layer [8, 24]. A brief outline of the integration procedure follows. The 3x3x0.3 mm \( \text{Si} \) microcavity chip is aligned and bonded to the desired location on the top surface of the atom chip using polymethyl methacrylate. The fiber taper is sup-
ported in a self-tensioning “U” configuration by a glass coverslip (~200 \( \mu \text{m} \) thick) as illustrated in Fig. 1(d). The taper is aligned with the microdisk using DC motor stages with 50 nm encoder resolution. Adjustment in the lateral gap between the taper and the microdisk is used to tune the level of cavity loading; owing to the excellent phase matching of the fiber taper guided mode to the whispering-gallery modes of the microdisk critical coupling was possible with a loaded \( Q \sim 10^6 \). The fiber taper and microdisk are then permanently attached using UV curable epoxy in two regions: (i) microscopic glue joints between the fiber taper and lithographically defined \( \text{SiN}_x \) supports (see Fig. 1(a)) fix the position of the taper relative to the disk, and (ii) microscopic glue joints be-
remained constant during the chamber pump-down, bake-out, and atom trapping, demonstrating the robustness of the fiber-cavity mounting. However, after the chamber bake, \( \lambda_0 \) was red shifted 0.11 nm from the pre-bake value and was found to increase logarithmically with exposure time to the Cs vapor as shown in Fig. 2(d). During subsequent chamber bakes and intermittent closures of the Cs source (for periods as long as 2 weeks) \( \lambda_0 \) was found to remain constant.

The logarithmic time dependence of \( \lambda_0 \) with Cs exposure suggests that the Cs coverage of the microdisk surface is saturating in a “glassy” manner [26]; interactions between deposed atoms quench the rate of adsorption. A shift \( \Delta \lambda_0 \) of the disk resonances can be related to a surface film thickness by \( s \sim \Delta \lambda_0 / (\lambda_0 (n_f - 1) \Gamma') \), where \( \Gamma' \) represents the fraction of modal energy in the film and \( n_f \) is the refractive index of the film. From finite element simulations of the microdisk, \( \Gamma' = 0.0026 \) nm\(^{-1} \) for the \( p = 1 \) TE-like mode. Assuming a film index of refraction equal to that of SiN, the measured wavelength shift at the longest measured time (\( t = 450 \) h) corresponds to roughly a half-monolayer coverage of Cs on the disk surface (monolayer thickness \( \sim 4 \AA \) [27]).

As a future method of compensating for resonant detuning of the microdisk mode due to variation in fabrication or the time-dependent Cs surface coverage, and as an initial demonstration of the scalability of the fiber-coupled microdisk chip concept, we show in Figure 3(a) a single fiber taper coupled in parallel to an array of 10 nominally identical microdisks (Fig. 3(b)). Over a \( \pm 0.25 \) nm wavelength range the fiber taper couples to 5 of the \( p = 1 \), TE-like modes as shown in Fig. 3(c), the remaining 5 modes lying within a \( \pm 1 \) nm range. A modest 10 °C of temperature tuning may be used to tune between the 5 closely spaced modes. Each of these resonances is due to coupling to a unique microdisk, as verified by imaging the scattered light from the microdisks as a function of wavelength.

In conclusion, we have shown that wavelength-scale high-\( Q \) microcavities can be realized from SiN, at near-visible wavelengths, and have demonstrated a method for integrating these devices with atom chips. The resulting optical fiber taper interface to the hybrid atom-cavity chip provides sufficient optical access for chip-based atom trapping and cooling while providing highly efficient optical coupling to single, or simultaneously to multiple, microdisk cavities. In the future, the use of SiN microcavities provides a path to a fully monolithic atom-cavity Si chip.

The authors thank M. Borselli and T. Johnson for assistance in FEM simulations and microdisk process development, and J. Kerckhoff for help with Cs adsorption measurements.
