Supersymmetric gauge theories on the lattice

I. Montvay

Deutsches Elektronen Synchrotron DESY, Notkestr. 85, D-22603 Hamburg, Germany

The perspectives of numerical simulations in supersymmetric quantum field theories with vector-like gauge symmetries are discussed. A numerical simulation algorithm for SU(2) gauge theory with gluinos is studied and the first results on the glueball-gluinoball spectrum are presented.

1. INTRODUCTION

Supersymmetric gauge theories may have fascinating non-perturbative properties. Previous attempts to understand them theoretically are mainly based on the instanton calculus (for a review and references see [1]). Recently, the $N=2$ extended gauge theories received particular interest because Seiberg and Witten were able to obtain exact results on their low energy effective action [2]. Besides the theoretical interest, there are also some interesting open questions concerning phenomenology. Although the most probable range of supersymmetry breaking mass parameters, as for instance the gluino mass, are at or above the 100 GeV range, the possibility of a light gluino with a mass near 1 GeV is not yet completely excluded [3]. In such a situation the extra hadronic states ("R-hadrons") could be hidden in the complicated "zoo" of normal hadronic states with masses above 1 GeV [4].

In a lattice formulation, most probably, one has to give up exact supersymmetry. This is certainly not surprising, because supersymmetry is an extension of the Poincaré symmetry, which is broken by the lattice. For instance, the supersymmetry generators $Q_{i\alpha}, \bar{Q}_{j\dot{\beta}}$ with internal indices $i,j$ and Weyl-spinor indices $\alpha, \dot{\beta}$ ($i,j = 1, ..., N$; $\alpha, \dot{\beta} = 1, 2$) obey the anticommutation relation

$$\{Q_{i\alpha}, \bar{Q}_{j\dot{\beta}}\} = 2\delta_{ij}\sigma_{\mu,\alpha\dot{\beta}}P_{\mu},$$

where the four-momentum $P_{\mu}$ ($\mu = 1, 2, 3, 4$) is the generator of translation symmetry, which is broken on the latticized space-time. This led Curci and Veneziano [5] to propose a lattice formulation of the $N=1$ supersymmetric Yang-Mills theory based on Wilson lattice fermions. The supersymmetry at zero gluino mass is then expected to be restored in the continuum limit, similarly to the axial symmetry in QCD at zero quark masses. The continuum limit at non-zero gluino mass is the corresponding theory with softly broken supersymmetry, which is actually the interesting case for phenomenology.

The similar lattice formulation of $N=2$ supersymmetry [6] is, on one hand, even simpler because there the gluino is a Dirac particle, in contrast to the $N=1$ case with Majorana gluinos. On the other hand, the $N=2$ supersymmetric Yang-Mills theory has some new generic features of supersymmetry, for instance, flat directions in the effective potential and asymptotically free Higgs mechanism. Theoretically very appealing is the automatically vector-like nature of $N=2$ SUSY, which is very welcome on the lattice, where the formulation of chiral gauge theories encounters great difficulties.

2. AN ALGORITHM FOR GLUINOS

Although the $N=2$ extended supersymmetry has many interesting theoretical features, it is better to start the non-perturbative lattice studies with the $N=1$ case, which is simpler.

2.1. Lattice action

The lattice action proposed in ref. [4] for the $N=1$ supersymmetric Yang-Mills theory is based on the Wilson action formulated for a
Dirac fermion in the adjoint representation. The fermionic part of this action is:

\[ S_f = \sum_x \left\{ \overline{\psi}_x \gamma^\mu \psi^\mu_x - K \sum_{\mu=1}^4 \left[ \overline{\psi}_{x+\mu} V_{x,\mu} (1 + \gamma_\mu) \psi^\mu_x \right. \right. \]
\[ \left. \left. + \overline{\psi}_x V^T_{x,\mu} (1 - \gamma_\mu) \psi^\mu_{x+\mu} \right] \right\} = \overline{\psi} Q \psi , \]

where the adjoint gauge field on links is

\[ V_{x,\mu} \equiv V_{x,\mu} [U] \equiv 2 \text{Tr}(U_{x,\mu}^\dagger T^r U_{x,\mu} T^s) , \]

and \( T_r (r = 1, 2, 3) \) denotes the SU(2) generators.

The two Majorana field components of the Dirac fermion field \( \psi \) are defined as

\[ \psi^{(1)} \equiv \frac{1}{\sqrt{2}} (\psi + C \overline{\psi}^T) , \]
\[ \psi^{(2)} \equiv \frac{i}{\sqrt{2}} (\psi - C \overline{\psi}^T) . \]

In terms of these we have:

\[ S_f = \frac{1}{2} \overline{\psi}^{(1)} Q \psi^{(1)} + \frac{1}{2} \overline{\psi}^{(2)} Q \psi^{(2)} . \]

Therefore a Majorana fermion corresponds to \( N_f = \frac{1}{2} \) number of flavours. As a consequence, in the bosonic path integral obtained by integrating out the Grassmann variables, the effect of a Majorana fermion is taken into account by the square root of the fermion determinant \( \sqrt{\det Q} \).

### 2.2. Two-step multi-bosonic algorithm

The numerical simulation of the \( N = 1 \) supersymmetric Yang-Mills theory with dynamical gluinos requires the generation of \( \sqrt{\det Q} \) in the bosonic path integral. Neglecting possible sign changes of \( \det Q \), we can set with \( Q \equiv \gamma_5 Q \)

\[ \sqrt{\det(Q)} = \sqrt{\det(Q^1 Q)}^{1/4} = \sqrt{\det(\widetilde{Q}^2)}^{1/4} . \]

In the framework of multi-bosonic algorithms [10], these can be approximated by the determinant of polynomials. In order to decrease the number of pseudofermionic boson fields, and hence the autocorrelation and the storage requirements, one can take a two-step approximation scheme [11]. The approximation up to a deviation norm \( \delta \) is then

\[ \{ \det \widetilde{Q}^2 \}^{1/4} \overset{\delta}{\rightarrow} \frac{1}{\det[P(Q^2)]} \det[P(Q^2)] . \]

Here the polynomial \( \widetilde{P}(x) \) is a crude approximation of the function \( x^{-1/4} \) in the interval \( x \in [\epsilon, \lambda] \) containing the spectrum of \( \widetilde{Q}^2 \). This approximation is then arbitrarily improved by the product of two polynomials \( \widetilde{P}(x) P(x) \). In the fermion simulation algorithm [8] the second factor \( P(x) \) is taken into account by a “noisy correction step”, as introduced in ref. [11]. (A similar correction scheme has been proposed in the multi-bosonic framework in ref. [10].) For the second polynomial one does not introduce bosonic fields, therefore no storage is needed. The autocorrelation is mainly determined by the order of the first polynomial, which can be kept low.

The definition of the deviation norm \( \delta \) for the necessary polynomial approximations has to allow for a flexibility in choosing functional forms, weight factors and approximation regions. This can be achieved by

\[ \delta \equiv \left\{ \int_\epsilon^\lambda dx [1 - x^\alpha P(x)]^2 \right\}^{1/2} , \]

where the function to be approximated is \( x^{-\alpha} \). The advantage of this choice is that \( \delta^2 \) is a quadratic form of the polynomial coefficients and hence the minimum can easily be found.

Compared to Chebyshev approximations, the polynomials minimizing \( \delta \) in (8) give somewhat less uniform relative deviations in the interval \( x = [\epsilon, \lambda] \). (Remember that the Chebyshev polynomials are minimizing the maximum of the relative deviation, the so called “infinity norm”.) However, in the present case the greater flexibility of the above quadratic scheme is more important.

### 3. NUMERICAL SIMULATION

There are several interesting questions which can be investigated by numerical simulations in the \( N = 1 \) supersymmetric Yang-Mills theory. For a first orientation the knowledge of the gluon-gluino-ball spectrum of hadronic states is very useful. In the supersymmetric limit there have to be degenerate supermultiplets. For non-zero gluino mass these multiplets are split up, and for infinite gluino mass only the glueballs of pure gauge theory remain in the physical spectrum.
It is plausible (but not absolutely necessary) that the lowest $0^+$ glueball state becomes a member of the lowest chiral supermultiplet, which also contains a Majorana spinor and a $0^-$ pseudoscalar boson. This latter can be most simply built from two gluinos. The Majorana spinor gluino-glueballs are obtained as bound states of a gluino with gluons.

### 3.1. First results on the spectrum

The two-step multi-bosonic algorithm has several parameters which have to be optimized in a given situation (depending on bare parameters, lattices etc.). In ref. [8] a first look on autocorrelations has been taken for the gauge group SU(2) at bare gauge coupling $\beta = 2.0$. (Another possible simulation algorithm based on classical dynamics type equations has recently been tested in ref. [11].) For an interesting spectrum calculation one has to go, however, to larger $\beta$-values.

In pure gauge theory the continuum behaviour starts to set in at $\beta = 2.3$. Therefore one can try first this value. For hopping parameter values $K = 0.14 - 0.15$ short autocorrelations could be achieved on $4^3 \cdot 8 - 8^3 \cdot 16$ lattices with the first polynomial $P$ of order $n = 10 - 12$ and second polynomial $P$ of order $n = 30 - 40$. The spectrum of $Q^IQ$ was well inside the interval $[0.02, 5.0]$.

Table 1

| $\beta$ | $K$ | $\sqrt{\sigma_2}$ | $M_{gg}$ | $M_{g\tilde{g}}$ |
|---------|-----|-------------------|-----------|-----------------|
| 2.30    | 0.140 | 0.53(1) | 1.34(19) | 2.90(12) |
| 2.30    | 0.150 | 0.54(1) | 0.85(23) | 2.78(13) |

The first results have been obtained on $4^3 \cdot 8$ lattice. The present statistics is based on 5000 updating cycles, where a cycle consisted of a few standard sweeps on every field variable. To monitor the string tension $\sigma$ I determined the $2 \otimes 2$ Creutz-ratio $\chi_2 \equiv W_{22}W_{11}/W_{12}^2$ and defined $\sigma_2 \equiv -\log \chi_2 \simeq \sigma$. The results for this and the lowest $0^+$ glueball state $(M_{gg})$ and gluino-glueball mass $(M_{g\tilde{g}})$ are contained in table 1. The signal for the gluino-gluino states can be obtained from noisy estimators [3], but this still needs some improvement, in order to obtain $M_{g\tilde{g}}$. First estimates based on the study of the spectrum of $Q$ indicate a critical hopping parameter $K_c \simeq 0.165$.

### 3.2. Future goals

Besides the spectrum, some other non-perturbative questions can be investigated which have also been recently discussed in the literature. Examples are: the phase structure based on exact $\beta$-functions [12], or the question of confinement versus screening at zero gluino mass [13]. These problems seem to be well suited for numerical simulation studies which are feasible with presently available computer resources.
