Abstract

Aims: Accumulating evidence suggests that patients with frontotemporal lobar degeneration (FTLD) can have pathologic accumulation of multiple proteins, including tau and TDP-43. This study aimed to determine the frequency and characteristics of concurrent tau pathology in FTLD with TDP-43 pathology (FTLD-TDP).

Methods: The study included 146 autopsy-confirmed cases of FTLD-TDP and 55 cases of FTLD-TDP with motor neuron disease (FTLD-MND). Sections from the basal forebrain were screened for tau pathology with phosphorylated-tau immunohistochemistry. For cases with tau pathology on the screening section, additional brain sections were studied to establish a diagnosis. Genetic analysis of \(C9orf72\), \(GRN\) and \(MAPT\) was performed on select cases.

Results: We found 72 cases (36%) with primary age-related tauopathy (PART), 85 (42%) with ageing-related tau astrogliopathy (ARTAG), 45 (22%) with argyrophilic grain disease (AGD) and 2 cases (1%) with corticobasal degeneration (CBD). Patients with ARTAG or AGD were significantly older than those without these comorbidities. One of the patients with FTLD-TDP and CBD had \(C9orf72\) mutation and relatively mild tau pathology, consistent with incidental CBD.

Conclusion: The coexistence of TDP-43 and tau pathologies was relatively common, particularly PART and ARTAG. Although rare, patients with FTLD can have multiple neurodegenerative proteinopathies. The absence of TDP-43-positive astrocytic plaques may suggest that CBD and FTLD-TDP were independent disease processes in the two patients with both tau and TDP-43 pathologies. It remains to be determined if mixed cases represent a unique disease process or two concurrent disease processes in an individual.

Abbreviations: AGD, argyrophilic grain disease; ARTAG, ageing-related tau astrogliopathy; CBD, corticobasal degeneration; FTLD, frontotemporal lobar degeneration; FTLD-tau, frontotemporal lobar degeneration with tau pathology; FTLD-TDP, frontotemporal lobar degeneration with TDP-43 pathology; H&E, haematoxylin and eosin; LATE-NC, limbic-predominant age-related TDP-43 encephalopathy neuropathological change; MND, motor neuron disease; NFT, neurofibrillary tangle; PART, primary age-related tauopathy; PSP, progressive supranuclear palsy; TDP-43, transactive response DNA-binding protein of 43 kDa.

INTRODUCTION

Frontotemporal lobar degeneration (FTLD) is pathologically and clinically heterogeneous and classified by the predominant protein that accumulates within neuronal and glial lesions. Most cases of FTLD have either transactive response DNA-binding protein of 43 kDa (TDP-43; FTLD-TDP, 50%) or tau inclusions (FTLD-tau, 45%), with a small number having inclusions of fused in sarcoma (FUS; FTLD-FUS, <5%) [1]. Patients with FTLD-TDP have various clinical presentations, including behavioural variant frontotemporal dementia, primary progressive aphasia and corticobasal syndrome. Familial FTLD-TDP is most often caused by mutations in C9orf72 or progranulin (GRN) [2]. Some patients with FTLD also develop motor neuron disease (MND; FTLD-MND). Accumulation of TDP-43 aggregates in the central nervous system is a common pathologic feature of both MND and FTLD; thus, both are considered part of a spectrum of TDP-43 proteinopathies [3,4].

FTLD-tau includes progressive supranuclear palsy (PSP), corticobasal degeneration (CBD) and Pick’s disease [5]. Intracellular aggregates of phosphorylated tau protein in neurons and glia associated with neurodegeneration are pathologic hallmarks of FTLD-tau [5]. Increased age is a common risk factor for neurodegenerative disorders. Age-related changes, such as cellular senescence, mitochondrial dysfunction and epigenetic alterations, have been reported in neurodegenerative processes [6–8]; thus, elderly individuals may often develop more than one neurodegenerative disease, with the accumulation of multiple types of pathological protein aggregates [9–12]. Indeed, concurrent TDP-43 pathology has been reported in a range of tauopathies, including Alzheimer’s disease [12,13], PSP [14–16] and CBD, [16–19] as well as synucleinopathies [20–22]. Our previous study found that 45% of CBD patients had TDP-43 pathology [19]. Some cases had extensive TDP-43 pathology in the neocortex, which can be considered a mixed FTLD-tau and FTLD-TDP. More recently, Kim et al [23], reported nine cases of mixed FTLD-TDP and FTLD-tau, in which three unclassifiable FTLD-tau and two PSP cases had a primary diagnosis of FTLD-TDP, while FTLD-TDP was found in four cases with CBD. These studies suggest that FTLD can be caused by coexisting TDP-43 and tau pathologies; however, the frequency and characteristics of tau and TDP-43 co-pathology have not been investigated.

In the present study, we aimed to determine the frequency and characteristics of tau pathology in a series of cases of FTLD-TDP and FTLD-MND that were considered ‘primary’ TDP-43 proteinopathies as their original neuropathologic diagnosis. To do this, we screened tau pathology in 146 patients with FTLD-TDP and 55 patients with FTLD-MND. All cases were from the Mayo Clinic brain bank for neurodegenerative disorders.

METHODS

Case selection

This study included 201 cases with FTLD-TDP with MND (N = 55) or without MND (N = 146) from 1998 to 2020. All brain autopsies were performed after consent of the legal next of kin or individual with power of attorney to grant permission. Studies of autopsy samples are considered exempt from human subjects research by Mayo Clinic Institutional Review Board.

General neuropathologic assessment

Formalin-fixed hemibrains underwent systematic and standardised sampling with neuropathologic evaluation by a single, experienced neuropathologist (D.W.D.). The whole brain weight was estimated by multiplying by two the weight of the available hemibrain. Regions sampled in all cases included six regions of the neocortex, two levels of the hippocampus, a basal forebrain section (including the amygdala, lentiform nucleus and hypothalamus), corpus striatum at the level of the nucleus accumbens, thalamus at the level of the subthalamic nucleus, midbrain, pons, medulla and two sections of the cerebellum, one including the deep nuclei. Paraffin-embedded 5-μm thick sections mounted on glass slides were stained with haematoxylin and eosin (H&E) and thioflavin S (Sigma-Aldrich, St. Louis, MO). Braak neurofibrillary tangle stage (NFT). Thal amyloid phase and severity of cerebral amyloid angiopathy were assigned using thioflavin S fluorescent microscopy according to previously described methods [24–28]. Immunohistochemistry for phosphorylated-TDP (pS409/410, mouse monoclonal, 1:5,000, Cosmo Bio, Tokyo, Japan) was performed on sections of cortex, hippocampus, basal forebrain, midbrain, medulla and cervical spinal cord to establish a neuropathological diagnosis of...
FTLD-TDP or FTLD-MND. The neuropathologic diagnosis of FTLD-MND required motor neuron loss with Bunina bodies and a variable degree of corticospinal tract degeneration, demonstrated with myelin stains (Luxol fast blue-periodic-Schiff) and immunohistochemistry for activated microglia (IBA-1, rabbit Ig, 1:3,000, Wako Chemicals, USA [29]). Hippocampal sclerosis was diagnosed when neuronal loss and gliosis were selective in the CA1 sector and/or subiculum of the hippocampus without other pathologic findings that could account for neuronal loss in this region.

Screening of tau pathologies

We immunostained 5-μm-thick sections of the basal forebrain section using a phosphorylated-tau antibody (phosphorylated-tau Ser202, CP13; mouse monoclonal; 1:1,000; a gift from the late Dr Peter Davies; Feinstein Institute for Medical Research). Following deparaffinisation in xylene and reagent alcohol, antigen retrieval was performed by steaming slides in distilled water for 30 min. Immunostaining was performed with an IHC Autostainer 480S (Thermo Fisher Scientific Inc., Waltham, MA) and DAKO EnVision™ + reagents (Dako, Carpinteria, CA). Immunostained slides were counterstained with haematoxylin and coverslipped. Tau-immunostained slides of all 201 cases were evaluated by three investigators (SK, XZ and DWD) blinded to clinical and pathological information. For cases suspected of having FTLD-tau based on the basal forebrain screening section, additional sections from the motor cortex, cingulate gyrus, superior frontal gyrus, thalamus/subthalamic nucleus, midbrain, pons and cerebellum were also processed for tau immunohistochemistry.

A diagnosis of CBD was made based on the presence of astrocytic plaques and numerous tau-positive threads in the grey and white matter in cortical and subcortical regions [30]. A diagnosis of argyrophilic grain disease (AGD) required tau-positive (argyrophilic) grains in medial temporal lobe structures (i.e., amygdala and hippocampus), accompanied by pretangles, coiled bodies, balloon neurons and granular/fuzzy astrocytes or bush-like astrocytes [31]. Silver stains (Gallyas) were used to confirm the diagnosis of AGD. For cases with AGD in the amygdala, additional sections from the hippocampus, entorhinal cortex, inferior temporal gyrus and cingulate gyrus were stained with tau immunohistochemistry and assessed to assign an AGD stage according to Saito et al [32]. The diagnosis of ageing-related tau astrogliopathy (ARTAG) was associated with variable thorn-shaped astrocytes or granular/fuzzy astrocytes in subependymal, subpial, perivascular, grey matter and white matter [33].

Clinical assessment

Clinical information was abstracted by two investigators (SK and AM) from the available medical records and brain bank questionnaires filled out by a close family member. The information included the age at symptom onset, disease duration, age at death, clinical diagnosis, clinical symptoms, neurological signs and family history of dementia or parkinsonism.

Genetic analysis

We performed genetic analyses in two patients with FTLD-TDP and CBD. For genotyping, genomic DNA was extracted from frozen cerebellum tissue using standard procedures. MAPT H1/H2 haplotype (SNP rs1052553 A/G, A = H1, G = H2) was assessed with TaqMan SNP genotyping assays (Applied Biosystems, Foster City, CA). Genotype calls were obtained with QuantStudio™ Real-Time PCR Software (Applied Biosystems). MAPT sequencing was performed in exons 7 and 9–13, as well as known pathogenic intronic mutations located at 50 bp on either side of each exon (e.g., IVS10 + 16 C > T). GRN sequencing and screening for C9orf72 hexanucleotide repeat expansion were performed as previously described [34,35].

Statistical analysis

All statistical analyses were performed using R 4.1.1. Fisher’s exact test was performed for group comparisons of categorical data, as appropriate. Mann–Whitney rank-sum test, analysis of variance (ANOVA) on ranks, followed by Steel-Dwass post hoc test, or one-way ANOVA, followed by post hoc Tukey test, was used for analyses of continuous variables as appropriate. P values <0.05 were considered statistically significant.

RESULTS

Summary of the cohort

The study set included 146 patients (84 men and 62 women) of FTLD-TDP and 55 patients (30 men and 25 women) of FTLD-MND (Table 1). The average age at death was significantly older in FTLD-TDP than in FTLD-MND (74 ± 10 vs. 67 ± 9 years; p < 0.001). FTLD-TDP also had a significantly longer disease duration than FTLD-MND (9 ± 5 vs. 4 ± 2 years; p < 0.001). The average formalin-fixed brain weight was significantly lower in FTLD-TDP than in FTLD-MND (970 ± 160 g vs. 1120 ± 170 g; p < 0.001). Alzheimer-type pathologies, measured by the Braak NFT stage and Thal amyloid phase, were not significantly different between the two groups.

Alzheimer’s-type pathology assessed by thioflavin S microscopy

Thioflavin S microscopy was used to assign Braak NFT stage: Braak stage 0 in 46 (23%), stage I in 40 (20%), stage II in 65 (32%), stage III in 28 (14%), stage IV in 14 (7%), stage V in 4 (2%) and stage VI in 4 patients (2%). Thal amyloid phase was also assigned using Thioflavin
S microscopy: Thal phase 0 in 106 (53%), phase 1 in 41 (20%), phase 2 in 23 (11%), phase 3 in 12 (6%), phase 4 in 7 (3%) and phase 5 in 12 (6%). Cerebral amyloid angiopathy was detected in 64 patients (61%). In this autopsy cohort, 72 patients (36%) had Braak stages I–IV and Thal amyloid phase 0, consistent with a diagnosis of primary age-related tauopathy (PART) [36]. The age at death was not significantly different between patients with and without PART (71 ± 9 vs. 73 ± 10 years; 0.194).

### Frequency of tau pathologies in TDP-43 proteinopathies

The second most common concurrent tau pathology was ARTAG, which was detected in 85 cases (42%) (Table 1). Subpial/subependymal type (36%) was the most frequent, followed by perivascular type (27%). On tau immunohistochemistry, thorn-shaped astrocytes were detected in subpial (Figure 1A) and perivascular spaces (Figure 1B) in the mediobasal forebrain and variably in the amygdala (Figure 1C). Thorn-shaped astrocytes were also observed in the peri-amygdaloid white matter (Figure 1D). The age at death was significantly older in cases with ARTAG than in those without ARTAG (76 ± 9 vs. 69 ± 10 years; \( p = 5.7 \times 10^{-7} \)), regardless of the disease group (i.e., FTLD-TDP, FTLD-MND; Figure 1E). A multivariable logistic regression model adjusting for age, sex, Braak NFT stage and Thal amyloid phase revealed that older age (OR 1.08; CI 1.04–1.12; \( p = 3.4 \times 10^{-5} \)), higher Braak NFT stage (OR 2.39; CI 1.24–4.61; \( p = 0.010 \)) and male sex (OR 1.33; CI 1.05–1.69; \( p = 0.018 \)) were independent risk factors for ARTAG.

AGD was detected in 45 cases (22%). Argyrophilic grains in the amygdala were accompanied by pretangles, coiled bodies, balloon neurons and granular/fuzzy astrocytes (Figure 1F–I). Screening of additional regions revealed that 23 cases had AGD restricted to the amygdala (stage 1), 15 also had AGD in the entorhinal cortex or subiculum (stage 2) and in 7 cases had pathology in the cingulate gyrus (stage 3). As with ARTAG, the age at death was significantly older in cases with AGD compared to cases without AGD (77 ± 10 vs. 71 ± 10 years; \( p = 9.1 \times 10^{-4} \)). As shown in Figure 1J, the median age at death was highest in stage 3, followed by stages 2 and 1. A multivariable logistic regression model adjusting for age, sex, Braak NFT stage and Thal amyloid phase revealed that older age (OR 1.05; CI 1.01–1.09; \( p = 0.017 \)) and higher Braak NFT stage (OR 1.33; CI 1.03–1.71; \( p = 0.026 \)) were independent risk factors for AGD.

We found two patients with tau pathology consistent with CBD (Table 2). Immunohistochemistry for tau revealed astrocytic plaques in the superior frontal gyrus and premotor cortex, tau-positive threads and coiled bodies in the adjacent white matter, and pretangles and threads in the subthalamic nucleus, pontine base, inferior olivary nucleus and cerebellar dentate nucleus in both patients (Table 3). One patient (case 2) also had AGD. The other patient, who had a family history of dementia (case 1), carried C9orf72 hexanucleotide repeat expansion. Mutations in GRN or MAPT were not detected in either patient. Clinical presentations of these patients were Alzheimer’s type dementia (case 1) and behavioural variant frontotemporal dementia (case 2). To adjudicate which pathology was most likely to contribute to their clinical presentations, we describe detailed pathologic findings and clinical features of these two cases. The detailed clinical history is provided in the supporting information.

---

Abbreviations: AGD, argyrophilic grain disease; ARTAG, ageing-related tau astrogliopathy; CBD, corticobasal degeneration; FTLD, frontotemporal lobar degeneration; MND, motor neuron disease; NFT, neurofibrillary tangle; PART, primary age-related tauopathy.
CASE 1

The fixed left hemibrain weighed 460 g. The macroscopic findings revealed minimal cortical atrophy in the frontal and temporal lobes, but there was atrophy of the corpus callosum and dilation of the lateral ventricles. Subcortical regions, brainstem and cerebellum were unremarkable except for decreased pigmentation in substantia nigra and locus coeruleus (Figure 2A–D).

On H&E-stained sections, the neocortex had mild spongiform change and gliosis, as well as mild thinning of the cortical ribbon, most marked in the frontal and temporal lobes. Only a few balloon neurons were detected in the cingulate gyrus. Immunohistochemistry for phosphorylated-TDP-43 showed neuritic processes and neuronal cytoplasmic inclusions (NCI) in the neocortex, most marked in superficial cortical layers (Figure 2E,F), consistent with FTLD-TDP type A [37]. A few neuronal intranuclear inclusions were also detected. TDP-43-positive fine neurites were present in the CA1 sector of the hippocampus, along with marked neuronal loss, consistent with hippocampal sclerosis (Figure 2G,H). The caudate nucleus and the nucleus accumbens had atrophy and gliosis, while the putamen and globus pallidus were less affected. Sparse NCI and dystrophic neurites were detected. The thalamus had mild atrophy and gliosis in the anterior and dorsomedial nuclei. The ventral and lateral thalamus and the subthalamic nucleus were unremarkable. The substantia nigra had marked neuronal loss and gliosis with extraneuronal neuromelanin, marked in the ventrolateral

FIGURE 1 Representative images of ARTAG and AGD. (A–D, F–I) Immunohistochemistry for CP13. (A–D) Numerous thorn-shaped astrocytes are observed in the subpial mediobasal region (A) and perivascular regions (B) and the grey matter (C) in the amygdala. Thorn-shaped astrocytes are also present in the peri-amygdaloid white matter (D). (E) Patients with ARTAG are significantly older than those without ARTAG across the three diseases. (F–I) The amygdala has numerous argyrophilic grains (F), along with balloon neuron (G), pretangles (H, arrows), coiled bodies (H, arrowhead) and granular-fuzzy astrocytes (I), consistent with AGD. (J) Patients with AGD (stages 1–3) are significantly older than those without AGD (stage 0) across the three diseases. Scale bars: 50 μm in A–D and F–I.
cell group. Moderate numbers of NCI, including skein-like inclusions, were present. The cerebral peduncle had atrophy and myelinated fibre loss in the corticobulbar tract, but not the corticospinal tract. The raphe nuclei had a mild neuronal loss, but the locus coeruleus was well populated. The medullary pyramid and hypoglossal nucleus were histologically unremarkable. The inferior olivary nucleus had severe gliosis. The substantia nigra had marked loss of pigment (Figure 3D).

On microscopic evaluation, the neocortex had thinning of the cortical ribbon with spongiform change and extensive gliosis, most marked in the frontal cortices, but sparing of the primary cortices and the occipital lobe. The gliosis was striking at the grey-white junction. The cingulate and frontal cortices had ballooned neurons (Figure 3E) on H&E-stained sections. Immunohistochemistry for phosphorylated-TDP-43 revealed neuritic processes, NCI (Figure 3F) and a few intranuclear inclusions (Figure 3G) in the neocortex, most marked in the frontal cortex, amygdala (Figure 3H), dentate fascia, pyramidal layer of the hippocampus, substantia nigra, red nucleus and inferior olivary nucleus. H&E staining showed severe neuronal loss and gliosis in CA1 and the subiculum. These findings were consistent with FTLD-TDP type A with hippocampal sclerosis [37]. There was also extensive atrophy of the basal ganglia and diffuse gliosis in the caudate nucleus and nucleus accumbens, while the globus pallidus was least affected. The anterior limb of the internal capsule had marked attenuation with myelinated fibre loss and gliosis. The thalamus, subthalamic nucleus and adjacent hypothalamus had marked gliosis. The mammillary body was atrophic and had many pyknotic neurons consistent with trans-synaptic degeneration. The posterior limb of the internal capsule was pale and gliotic. The substantia nigra had marked neuronal loss with extraneuronal neuromelanin and gliosis. Sparse TDP-43-positive NCI and dystrophic neurites were present. The cerebral peduncle had atrophy and gliosis of the corticobulbar tract. The raphe nuclei, locus coeruleus, reticular formation, medullary pyramid and hypoglossal nuclei were histologically unremarkable. The inferior olivary nucleus had severe gliosis with many TDP-43-positive NCI.

Immunohistochemistry for phosphorylated-tau revealed tau-positive threads and astrocytic plaques in the neocortex (Figure 3I,K), as well as numerous threads and fewer coiled bodies in cerebral white matter (Figure 3J,L) consistent with CBD. Abundant pretangles and threads were present in the subthalamic nucleus, red nucleus, pontine nuclei, inferior olivary nucleus and dentate nucleus (Figure 3M,Q), but the neuronal populations in these regions were relatively well preserved. Argyrophilic grains and pretangles were observed in the amygdala, hippocampus, ventral striatum and cingulate gyrus (Figure 3R), consistent with AGD.
cases raise the issue of which should be considered the coexistence of FTLD-TDP and FTLD-tau is uncommon [23]. Note: Semi-quantitative scores of tau lesions indicate --, none; +, sparse; ++, moderate; ++++, frequent for N, A, C and T. For argyrophilic grain, -- indicates absence, and + indicates presence.

Abbreviations: A, astrocytic lesion; C, coiled body; G, argyrophilic grain; N, pretangle/globose tangle; T, tau-positive thread.

In this series of 201 autopsy cases of TDP-43 proteinopathies, many patients had concurrent tau pathologies. Not unexpectedly, ARTAG (42%) and PART (36%) were the most frequent tau pathologies, followed by AGD (22%). In addition, we found two patients with CBD, which is a four-repeat tauopathy form of FTLD-tau. TDP-43 and tau are the most common molecular subtypes of FTLD, but the coexistence of FTLD-TDP and FTLD-tau is uncommon [23]. These cases raise the issue of which should be considered the ‘primary’ pathologic process and which should be considered the ‘secondary’ process. Case 1 was clinically diagnosed with familial AD based upon his cognitive impairment, initially characterised by amnestic type dementia, as well as dementia in multiple family members. Neuropathologic assessment revealed mild Alzheimer’s-type pathology (Braak NFT stage III and Thal amyloid phase 3) insufficient to account for dementia. Although the cortical atrophy of the frontal and temporal lobes was relatively mild, immunohistochemistry for TDP-43 and presence of C9RANT inclusions were diagnostic of FTLD-TDP [38]. A hexanucleotide repeat expansion in the C9orf72 gene was confirmed with repeat-primed polymerase chain reaction assay [35]. The presence of a pathogenic mutation in a gene for FTLD makes a strong case for the primary diagnosis in the case to be FTLD-TDP. Of note, amnestic Alzheimer’s dementia is a common clinical diagnosis of genetically confirmed FTLD-TDP in elderly individuals [39,40], and in an autopsy series from the State of Florida brain bank, late onset patients with C9orf72 mutations often present with Alzheimer type dementia or Lewy body dementia [41].

Tau pathology in this patient was consistent with CBD based upon morphology and neuroanatomical distribution; however, tau pathology was mild and subcortical nuclei vulnerable to neuronal loss in CBD, such as the globus pallidus and substantia nigra, were well preserved. Moreover, the severity of tau pathology was mild in subcortical regions. These findings are like those reported as ‘preclinical’ CBD [42]. In the current situation, the term ‘preclinical’ is not appropriate since the patient presented with cognitive impairment, behavioural changes and parkinsonism. Taken together, genetically confirmed FTLD-TDP with ‘incidental’ CBD seems to be the best neuropathologic diagnosis. Interestingly, this patient is like a patient in the study of Kim and co-workers. Their patient had FTLD-TDP type A and unclassifiable FTLD-tau with C9orf72 mutation (case 1) [23]. Given that C9orf72 mutation is the most common risk factor for familial amyotrophic lateral sclerosis and FTLD, its strong association with TDP-43 pathology has been established. In contrast, it is still unknown whether C9orf72 mutation is also associated with FTLD-tau. Bliek et al [43]. investigated Alzheimer’s-type tau pathology in the temporal cortex and hippocampus in patients with FTLD who carried C9orf72 mutation (c9FTLD) and found that tau pathology burden was not different between c9FTLD and sporadic FTLD. Snowden et al [44]. screened for C9orf72 mutations in 398 patients with clinical presentations of frontotemporal dementia and found one patient who had CBD pathology without TDP-43 pathology. The absence of TDP-43 pathology raised the question of the significance of C9orf72 hexanucleotide expansion in this patient. King et al [45]. reported a patient with C9orf72 mutation who had Pick’s disease and TDP-43 pathology, with TDP-43 co-localising with Pick bodies. This patient also had a MAPT variant A239T, which has not been associated with tau pathology. Taken together, the association between C9orf72 mutation and tau pathology remains uncertain and warrants further investigation.
Our second case had marked atrophy in frontal and temporal lobes, as well as severe atrophy in the orbital gyrus and caudate nucleus, and hippocampal sclerosis consistent with FTLD-TDP. In contrast, marked pigment loss in the substantia nigra and discoloration of the globus pallidus were suggestive of CBD. TDP-43 immunohistochemistry revealed moderate NCI and dystrophic neurites and sparse neuronal intranuclear inclusions in the neocortex, consistent with FTLD-TDP type A. There were neuronal cytoplasmic inclusions, dystrophic neurites and neuronal intranuclear inclusions in the midfrontal cortex (E) and inferior temporal cortex (F), consistent with FTLD-TDP type A. (G) CA1 sector of the hippocampus has neuronal cytoplasmic inclusions and numerous fine neurites, accompanied by neuronal loss (H), consistent with hippocampal sclerosis. (I) Numerous inclusions are C9Rant-positive in the cerebellar granular layer. Astrocytic plaques are present in the motor cortex (J, K) and superior frontal cortex (L). A mild degree of pretangles and threads are present in the subthalamic nucleus (M), pontine base (N), inferior olivary nucleus (O) and cerebellar dentate nucleus (P). Scale bars: 1 cm in C, 50 μm in E-P.

Our second case had marked atrophy in frontal and temporal lobes, as well as severe atrophy in the orbital gyrus and caudate nucleus, and hippocampal sclerosis consistent with FTLD-TDP. In contrast, marked pigment loss in the substantia nigra and discoloration of the globus pallidus were suggestive of CBD. TDP-43 immunohistochemistry revealed moderate NCI and dystrophic neurites and sparse neuronal intranuclear inclusions in the neocortex, consistent with FTLD-TDP type A. There was also severe tau pathology in the grey and white matter of the neocortex, deep grey nuclei, brainstem and cerebellum, consistent with CBD. Given that both FTLD-TDP and CBD can present as behavioural variant frontotemporal dementia, it is difficult to determine which pathology is ‘primary’ for this patient. One can argue that CBD is the ‘primary’ diagnosis in this patient and that TDP-43 pathology can be explained by limbic-predominant age-related TDP-43 encephalopathy neuropathological change (LATE-NC) [46]. LATE-NC is characterised by TDP-43 proteinopathy in the medial temporal lobe in the elderly with or without hippocampal sclerosis [46]. The amygdala and hippocampus are the most vulnerable regions, but the midfrontal gyrus is affected in stage 3; therefore, it is challenging to differentiate FTLD-TDP and advanced stages of LATE-NC [47]. Case 2 had significant frontal lobe atrophy, which supports the diagnosis of FTLD-TDP; however, frontal lobe atrophy is also common in CBD. The advanced age of the patient (84 years) and the presence of hippocampal sclerosis may also support the diagnosis of LATE-NC. In this sense, a diagnosis of CBD with LATE-NC could be reasonable. Nevertheless, our final neuropathological diagnosis is FTLD-TDP with ‘incidental’ CBD because atrophy of the globus pallidus and subthalamic nucleus were relatively mild compared to that of the orbital gyrus and caudate nucleus. We judge the CBD to be ‘incidental’ pathology in the context of FTLD-TDP.
The present study needs to consider the fact that TDP-43 pathology can be found in a subset of CBD cases. Our previous study identified astrocytic plaque-like TDP-43 lesions in the motor cortex and superior frontal gyrus in CBD patients with TDP-43 pathology. Therefore, we assumed that TDP-43 pathology was ‘secondary’ to CBD pathology [19]. In contrast, the two patients in the present study did not have astrocytic plaques with TDP-43 immunoreactive processes.

This finding supports the conclusion that TDP-43 pathology occurs independently from tau pathology in CBD, not ‘secondary’ to tau pathology.

A limitation of this study is that the clinical information of two patients with FTLD-TDP and CBD was limited due to the retrospective nature of the autopsy cohort. Systematic, longitudinal data with neurological examinations and neuropsychological testing were not available for these patients.
available. Motor symptoms suggestive of corticobasal syndrome may have been overlooked or not well documented. Another limitation is that we did not assess clinical features in patients with PART, ARTAG or AGD because the primary focus was FTLD-tau, rather than these ‘age-related’ tau pathologies.

In conclusion, by screening for tau pathology in TDP-43 proteinopathies, we identified two patients with mixed FTLD-TDP and CBD that are likely independent (‘co-primary’) disease processes. Many of elderly individuals with neurodegenerative disorders have multiple coexisting pathologies [11,12]; therefore, both TDP-43 and tau should be part of the screening process for the neuropathologic assessment of FTLD. We are not able to determine the relative contribution of each pathology to the clinical presentations in these patients. This is not too dissimilar to the issue of assigning relative contributions of mixed pathology in other settings, for example, cases with both Alzheimer’s disease and diffuse Lewy body disease. Implementation of molecular imaging modalities for each protein may help determine the timing and relative contributions of the proteins to clinical presentations.

ACKNOWLEDGEMENTS
We would like to thank the patients and their families who donated brains to help further the scientific understanding of neurodegeneration. The authors would also like to acknowledge Virginia Phillips, Jo A. Landino Garcia and Ariston L. Librero (Mayo Clinic, Jacksonville) for histologic support and Monica Castanedes-Casey (Mayo Clinic, Jacksonville) for immunohistochemistry support. This work is supported by CurePSP, the Rainwater Charitable Foundation and the Jaye F. and Betty F. Dyer Foundation Fellowship in progressive supranuclear palsy research, as well as National Institute of Neurological Disorders and Stroke (NINDS) Tau Center without Walls (U54-NS100693).

CONFLICT OF INTEREST
The authors declare no conflict of interest.

ETHICS STATEMENT
Brain autopsies were obtained after consent of the legal next of kin or individuals with legal authority to grant autopsy permission. De-identified studies of autopsy samples are considered exempt from human subject research by the Mayo Clinic Institutional Review Board.

AUTHOR CONTRIBUTIONS
Shunsuke Koga, Xiaolai Zhou, and Dennis W. Dickson contributed to the study concept and design, and to the analysis, acquisition and interpretation of data. Shucuke Koga performed statistical analyses, prepared figures, and drafted the manuscript. Xiaolai Zhou and Dennis W. Dickson edited the manuscript. Aya Murakami contributed to the acquisition, analysis, and interpretation of data, as well as review and critique of the manuscript. Matthew C. Baker contributed to the acquisition, analysis, and interpretation of data, as well as review and critique of the manuscript. Rosa Rademakers contributed to review and critique of the manuscript.

DATA AVAILABILITY STATEMENT
The data that support the findings of this study are available from the corresponding author upon reasonable request.
