(Dated: October 29, 2014)

The collective interference of partially distinguishable bosons in multi-mode networks is studied via double-sided Feynman diagrams. The probability for many-body scattering events becomes a multi-dimensional tensor-permanent, which interpolates between distinguishable particles and identical bosons, and easily extends to mixed initial states. The permanent of the distinguishability matrix, composed of all mutual scalar products of the single-particle mode-functions, emerges as a natural measure for the degree of interference: It yields a bound on the difference between event probabilities for partially distinguishable bosons and the idealized species, and exactly quantifies the degree of bosonic bunching.

I. INTRODUCTION

Few physical problems fit in the categories of computational complexity theory [1]. An outstanding example for a fruitful interface between physics and computer science is Boson-Sampling [2], the simulation of many indistinguishable bosons that scatter through a randomly chosen linear network with many more modes than particles: As a physical problem [3], it is implemented straightforwardly with single photons [3–5], as demonstrated experimentally [6–9]. Mathematically, the probability for an output event equates the absolute square of the permanent of the scattering sub-matrix, which has well characterized complexity [2, 10–13]. The simplicity of the mathematical expression for the observable physical quantity ensures that Boson-Sampling remains simple enough to allow strong complexity-theoretic statements: It is very likely too complex to be solved approximately for any classical computer in polynomial time in the number of particles [2]. Whether a functional scalable Boson-Sampler jeopardizes the extended Church Turing thesis [68] is under debate [14, 15], but consensus exists that Boson-Sampling constitutes a paradigm for a classically hard computational problem that is efficiently solved by a quantum physical system.

From a physical perspective, the successful experimental implementation of Boson-Sampling [2–9] has raised questions encompassing the scalability [16] and tolerance towards errors [15, 17, 18], the generalization to experimentally more accessible systems [20, 21] and alternative physical implementations of the original problem [22–26]. Bridging the fields of physics and computer science, the problem of verifying the functionality of an alleged Boson-Sampler arose [27, 28]. While from a skeptical computer-science perspective, an efficient, loophole-free and unambiguous certification is impossible [27, 28], there are plausible certification methods based on physical properties such as bosonic statistics [30], probabilistic Bayesian reasoning [31] and analytically solvable instances [5, 32].

The conditions assumed to establish the hardness of Boson-Sampling [2] – low particle density, indistinguishable bosons, and random scattering matrix – are crucial, since their violation enables efficient approximations: In the high-density limit of many more bosons than modes, semi-classical approaches become efficient [33, 34]. For distinguishable particles, one speaks of classical sampling, which can be simulated inexpensively with a naive Monte-Carlo method that treats particles independently, one after another [5, 11]. When artificial symmetries structure the scattering matrix, selection rules efficiently predict the strict suppression of certain output events [5, 35]. In these examples, physical intuition and the understanding of computational complexity nicely complement each other [36].

Here, we pave the road to study the distinguishability transition that connects ideal Boson-Sampling and its classical counterpart with distinguishable particles. On the one hand, the description of experiments requires a thorough understanding of such intermediate situation, because the indistinguishability of interfering bosons can be ensured only to a certain degree. On the other hand, numerous fundamental open questions regarding partially distinguishable particles remain: How complex is the sampling problem on the transition between the classical and the boson-sampler? Is there an unambiguous general quantifier of interference capability? Can one predict how “close” a situation resembles the classical or the bosonic setup, and estimate the error due to neglecting or idealizing bosonic interference?

Treatments of partially distinguishable particles formulated in the pure-state formalism [5, 37–44] are not ideally suited to answer these questions, as they suffer from computational costs and interpretational problems, exposed in Section II. The many-particle scattering probability has more manageable expressions within the recently introduced density-matrix approach [45], which naturally encompasses mixed initial states. Taking this method [45] as a starting point, we focus on pure initial states in Section III, present the – to our knowledge – most efficient algorithm for the computation of probabilities of pure partially distinguishable particles, and propose an interpretation based on double-sided Feynman diagrams. In Section IV a quantitative measure for the degree of interference is introduced, the permanent of the positive-definite hermitian distinguishability matrix, which yields bounds on the difference between
the event probabilities for bosonic or distinguishable and partially distinguishable particles under certain assumptions. Furthermore, this measure exactly quantifies the enhancement of bunching events with all particles in one output port, and restricts the total variation distance between the respective probability distributions. The formalism allows us to explore and understand several counter-intuitive features of partially distinguishable particles: Perfect cancellation of amplitudes is not restricted to ideal bosons, but also occurs for partially distinguishable particles, as discussed in Section III B. Furthermore, simplistic intuitive Ansätze that interpolate between indistinguishable and distinguishable particles are ruled out in Section V. Partially distinguishable situations do not resemble neither of the extreme cases, nor any mixture between them.

II. PARTIALLY DISTINGUISHABLE PARTICLES

Partially distinguishable particles have been treated by generalizing the bosonic permanent and the fermionic determinant to immanants [46–48]. Alternatively, the initial many-body state can be decomposed into a sum of orthogonal terms with well-defined degrees of distinguishability, such that any two particles will either perfectly interfere or not at all [49]. Recently, an approach based on the density-matrix formalism was proposed [45, 49], on which our calculations further below are based.

The tools used in Refs. [46–48] to generalize the bosonic permanent to the immanant are admittedly a beautiful application of group theory and make the symmetry breaking due to partial distinguishability tangible and illustrative. As pointed out in Ref. [45], however, these methods are not easily scalable, but force us to establish the transition probabilities anew for each particle number. As shown in Section II B below, the orthonormalization of the single-particle mode functions [45] reliably yields the desired many-particle transition probability in a scalable way, but it comes with high computational costs, interpretational issues, and without any straightforward generalization to mixed initial single-particle states. The complicated formulation aggravates any attempt to establish the actual computational complexity of the problem.

A. Scattering scenario

Closely following the physical scenario exposed in Refs. [2, 3, 49], consider \( n \) bosons prepared in the input modes of a scattering setup characterized by a unitary \( m \times m \) matrix \( U \). The initial distribution of the particles is defined by the mode occupation list \( \vec{r} = (r_1, \ldots, r_m) \) [49], where \( r_j \) particles populate input mode \( j \). We are interested in the probability to find the final state \( \vec{s} = (s_1, \ldots, s_m) \) in the output modes, where \( 0 \leq s_j, r_j \leq n, \sum_j s_j = \sum_j r_j = n \). Since unoccupied input and output modes are irrelevant for the fate of the particles, we define the effective scattering matrix \( M \) as the relevant submatrix of \( U \) that contains those rows and columns corresponding to initially and finally populated modes, such that the multiplicity of rows and columns equates the respective population. Using the mode assignment list \( \vec{d}(\vec{s}) = (d_1, \ldots, d_n) \) [49], which indicates the mode in which the \( j \)th particle resides, the effective scattering matrix becomes

\[
M = U_{\vec{d}(\vec{r}), \vec{d}(\vec{s})},
\]

where our convention identifies the \( j \)th row (column) with the \( j \)th input (output) mode, as illustrated in Fig. 1a.

Boson-Sampling [2, 3, 5] constitutes a special instance of this general scattering problem: Each input mode is populated by at most one boson and \( m \gg n \), which makes events with more than one particle per output mode improbable. The unitary scattering matrix \( U \) is picked randomly, weighted by the Haar-measure. The resulting effective scattering matrix \( M \) has no repeated rows and columns or any other structure, which impedes any simplification of the problem based on such possible multiplicity - a mandatory pre-requisite for the argument that Boson-Sampling is computationally hard.

In the experiment, particles are typically not perfectly identical, but they carry degrees of freedom by which they can be distinguished to a certain extent. Distinguishability is described in the most general fashion by pooling all possibly distinguishing degrees of freedom of the particles in the \( j \)th input mode into an “internal” state \( |\Phi_j\rangle \) (particles in the same spatial mode are fully indistinguishable, which is fulfilled well in experiments with photons). In other words, \( |\Phi_j\rangle \) contains all information that may potentially allow to distinguish the particle in mode \( j \) from a particle in another mode \( k \) other than the mode number itself, e.g. frequency, polarization, time of arrival or spin. The mutual distinguishability of each of the \( (n-1)n/2 \) possible pairs out of \( n \) particles is encoded in the hermitian positive-definite \( n \times n \) distinguishability matrix,

\[
S_{j,k} = \langle \Phi_{d_j(r)} | \Phi_{d_k(r)} \rangle,
\]

where \( S_{j,j} = 1 \). The multiplicity of rows and columns in the distinguishability matrix are equal and reflect the multiple occupation of input modes. For \( S = \mathbb{E} \) with \( \mathbb{E}_{j,k} = 1 \) for all \( j \) and \( k \), the problem reduces to idealized boson-sampling, all particles are perfectly identical; fully distinguishable particles, as they occur in classical sampling, are characterized by \( \langle \Phi_{j} | \Phi_{k} \rangle = \delta_{j,k} \), i.e. \( S = \mathbb{I} \). The approaches in Refs. [44, 45, 48] also introduce matrices to quantify distinguishability (see Eq. (C2) in [48], Eq. (6) in [45] and Eqs. (20),(22) in [44]), the four definitions differ formally; for pure states, however, they contain the same information and can be related to each other.
FIG. 1: (a) Scattering matrix. Particles prepared in \( r = (1, 0, 1, 0, 1) \) scatter off the setup described by a matrix \( U \); they are measured in the final configuration \( \vec{s} = (1, 0, 1, 0, 1) \). The submatrix \( M \) [Eq. (1)] is highlighted in dark blue. For convenience of notation, we re-label the occupied modes from 1 to \( n \), depending on the initial and final state. Rows (columns) correspond to amplitudes related to input (output) modes. (b) Orthonormalization of a generic many-body state with three partially distinguishable particles, Eq. (7). The two components highlighted by dashed lines contribute to the same final state, interference between them needs to be taken into account. (c) Ambiguity of the fully indistinguishable weight \( W_{\text{id}} = \langle \phi_1 | \phi_2 \rangle \langle \phi_1 | \phi_3 \rangle \), Eq. (10). Using the upper labeling, we find \( W_{\text{id}} = \frac{1}{n!} \); re-labeling the states as in the row below leads to \( W_{\text{id}} = 0 \). In other words, the projection of all vectors onto \( |\phi_i\rangle \) depends on the labeling of the vectors. The figure reproduces elements from [5].

Having established the physical setup, we formulate the scattering problem: The initial quantum state

\[
|\Psi_{\text{ini}}\rangle = \prod_{j=1}^{m} \frac{1}{\sqrt{r_j!}} \left( \hat{A}_{j,|\Phi_j\rangle} \right)^{r_j} |0\rangle \\
= \frac{1}{\sqrt{\prod_{k=1}^{n} r_k}} \prod_{j=1}^{n} \hat{A}_{d(\vec{r}_j),|\Phi_d(\vec{r}_j)\rangle} |0\rangle, \tag{3}
\]
evolves via the single-particle transformation

\[
\hat{a}_{j,|\Phi_j\rangle}^\dagger \rightarrow \sum_{k=1}^{m} U_{j,k} \hat{B}_{k,|\Phi_k\rangle}, \tag{4}
\]
into the final state

\[
|\Psi_{\text{fin}}\rangle = \hat{U} |\Psi_{\text{ini}}\rangle. \tag{5}
\]

Our object of interest is the probability \( \mathcal{P}_S(\vec{s}) \) to find the output configuration \( \vec{s} \) for particles characterized by \( S \). Our notation omits the initial configuration \( \vec{r} \), which is assumed to be fixed. For convenience, occupied input and output modes are relabeled by 1,\ldots,\( n \), i.e. \( \hat{a}_k \equiv \hat{A}_{d_k(\vec{r})} \hat{b}_{k,|\Phi_k\rangle} = \hat{B}_{d_k(\vec{s})} \hat{b}_{k,|\Phi_k\rangle} = \langle \Phi_{d_k(\vec{r})} | \Phi_k \rangle \), which amounts to formally assuming \( \vec{r} = \vec{s} = (1, 0, 1, 0, 1, 0) \) [Fig. 1(a)]. This convention makes all appearing expressions easier to read.

B. Treatment via selected single-particle basis

In the following, we argue that no single-particle basis allows a satisfactory treatment of the problem in the pure-state formalism: Given a single-particle basis \( \{|\eta_1\rangle, \ldots, |\eta_n\rangle\} \) that spans the generally \( n \)-dimensional internal Hilbert-space containing \( \{|\phi_1\rangle, \ldots, |\phi_n\rangle\} \), each \( |\phi_k\rangle \) in Eq. (3) is a superposition of all \( |\eta_j\rangle \), which makes the many-body state (3) a sum of \( n^n \) orthogonal terms. The number of non-vanishing terms in this expansion is reduced to \( n! \) by selecting the basis \( \{\tilde{\phi}_1, \ldots, \tilde{\phi}_n\} \) obtained via Gram-Schmidt-orthonormalization of \( \{\phi_1, \ldots, \phi_n\} \) [5, 41–43], which ensures that \( k > l \Rightarrow \langle \tilde{\phi}_k | \tilde{\phi}_j \rangle = 0 \). In particular, if the \( n \) particles only span a \( D < n \)-dimensional Hilbert space, at most \( D^{(n-D)} D! \) orthogonal terms remain. Formally, by writing the single-particle states as linear combinations of the \( |\tilde{\phi}_k\rangle \),

\[
|\phi_j\rangle = \sum_{k=1}^{j} c_{j,k} |\tilde{\phi}_k\rangle, \tag{6}
\]
we express the full many-body state (3) as

\[
|\Psi_{\text{ini}}\rangle = \sum_{j_2=1}^{2} \sum_{j_3=1}^{3} \sum_{\ldots} \sum_{j_n=1}^{n} \hat{a}_{j_1,|\Phi_{j_1}\rangle} \hat{a}^\dagger_{j_2,|\Phi_{j_2}\rangle} \hat{a}^\dagger_{j_3,|\Phi_{j_3}\rangle} \ldots \hat{a}^\dagger_{j_n,|\Phi_{j_n}\rangle} |0\rangle. \tag{7}
\]

The orthonormality of the \( |\tilde{\phi}_k\rangle \) then allows us to write the probability for the event \( \vec{s} \) as

\[
\mathcal{P}_S(\vec{s}) = \sum_{j_2=1}^{2} \sum_{j_3=1}^{3} \sum_{\ldots} \sum_{j_n=1}^{n} \langle \Psi_{\text{fin}}(\vec{j}, \sigma) | \hat{U} |\Psi_{\text{ini}}\rangle^2, \tag{8}
\]
where the sums over the \( j_k \) take into account all configurations of particles in orthonormalized internal states that are found in the output ports and

\[
|\Psi_{\text{fin}}(\vec{j}, \sigma)\rangle = \hat{N}(\vec{r}, \sigma) \prod_{k=1}^{n} \hat{b}_{k,|\tilde{\phi}_k\rangle} |0\rangle, \tag{9}
\]
is the final state with the particles in the internal states \( \{|\tilde{\phi}_1\rangle, |\tilde{\phi}_2\rangle, \ldots, |\tilde{\phi}_n\rangle\} \) distributed among the output ports according to the permutation \( \sigma \), where \( \hat{N}(\vec{r}, \sigma) \) accounts for the overnormalization due to output modes occupied by several indistinguishable particles. In evaluating (8), the terms in the initial and final states that do not contain the same set of single-particle states \( \{|\tilde{\phi}_1\rangle, |\tilde{\phi}_2\rangle, \ldots, |\tilde{\phi}_n\rangle\} \) vanish. A generalization of Eq. (8) to any basis \( \{|\eta_1\rangle, \ldots, |\eta_n\rangle\} \) was recently presented in [44].

Although the evaluation based on (8) can be scaled to reasonably large particle numbers [32] and allows a visual interpretation in terms of Feynman diagrams [5], there are four main caveats that make it unsatisfactory: In the first place, no clear physical interpretation of the
weights \( c_{j,k} \) is possible, as these are basis-dependent. In particular, it is tempting to interpret the amplitude of the fully indistinguishable component in Eq. (7),

\[
W_{id} = \prod_{j=2}^{n} |c_{j,1}|^2,
\]

(10)
as the “perfectly interfering” part of the wavefunction; this weight can, indeed, be used to formulate bounds to the deviation from the ideal probability distribution \([32]\). However, the set \( \{ |\phi_1\rangle, \ldots, |\phi_n\rangle \} \) depends on the ordering of vectors on which the orthonormalization is performed and the weight (10) varies considerably with the respective choice of basis. As an extreme example, sketched in Fig. 1(c), consider

\[
|\phi_1\rangle = |0\rangle, |\phi_2\rangle = \frac{|0\rangle + |1\rangle}{\sqrt{2}}, |\phi_3\rangle = \frac{|0\rangle - |1\rangle}{\sqrt{2}},
\]

(11)
where \(|0\rangle, |1\rangle\) denote any qubit-like degree of freedom, for which the weight of the fully indistinguishable component becomes \( W_{id} = 1/4 \). Exchanging the labels of the first and second ports does manifestly not modify the actual physical situation,

\[
|\phi_1\rangle = \frac{|0\rangle + |1\rangle}{\sqrt{2}}, |\phi_2\rangle = |0\rangle, |\phi_3\rangle = \frac{|0\rangle - |1\rangle}{\sqrt{2}},
\]

(12)
but leads to \( W_{id} = 0 \). In other words, a set of weights \( c_{j,k} \) does not allow any immediate quantitative statement on the degree of interference in the system.

As a second point, although all summands that contribute to the initial state in Eq. (7) are orthogonal, several feed the same final state: For \( n = 3 \), the components with weights \( c_{2,1}c_{3,2} \) and \( c_{2,2}c_{3,1} \) contain the same set of single-particle states \( \{ |\phi_1\rangle, |\phi_2\rangle \} \), and both contribute to the same final states [see Fig. 1(b)] \([4]\). As a consequence, interference between these two terms occurs and event probabilities depend on the relative phase between \( c_{2,1}c_{3,2} \) and \( c_{2,2}c_{3,1} \). The initial Fock-state \([3]\), however, is free of any phase relationship between the input modes, which makes the emerging relative phase a formal artifact, which further complicates the interpretation of the actual physical process. Summarizing these two points, the coefficients \( c_{j,k} \) do not bear clear physical meaning, they emerge as formal but unavoidable intermediate step between the physically meaningful scalar products and the observable event probabilities. Due to the orthonormalization, the dependence of the \( c_{j,k} \) on scalar products is intricate and obfuscates the behavior of event probabilities.

Thirdly, the computational expenses required to treat Eq. (8) are considerable: Not only does each scalar product \( \langle \Psi_{in}(j,\sigma)|\hat{U}|\Psi_{in}\rangle \) involve at least one permanent, but we also need to consider the superposition of terms in \( |\Psi_{in}\rangle \) that lead to the same final state. The total number of separable final states in the sum \([5]\) is \( n! \); since each of the \( n! \) appearing permanents requires an exponentially large number of operations, the total expenses scale dramatically. A precise quantification of the computational expenses for an approximate evaluation is difficult, as the number of terms depends on the chosen basis.

As a fourth and last point, the extension to mixed states is not straightforward: For a mixture of internal states at input mode \( j \), \( \hat{\psi}_j = \sum_k p_{j,k} |\psi_{j,k}\rangle \langle \psi_{j,k}| \), the orthonormalization needs to be performed for each set of pure states \( \{ |\psi_{1,k_1}\rangle, |\psi_{2,k_2}\rangle, \ldots, |\psi_{n,k_n}\rangle \} \). For mixed states with high rank, the emerging Hilbert space can have dimension much larger than \( n \).

Given these caveats, the question naturally arises whether there exists an optimal basis \( \{ |\eta_1\rangle, \ldots, |\eta_n\rangle \} \) that remains free of the above problems. For example, for \( n = 3 \), we impose that there be only 5 orthogonal terms in the decomposition \([7]\) into single-particle states \( |\eta_j\rangle \). As one quickly realizes by imposing these requirements as boundary conditions, there is, in general, no basis with these desirable properties for \( n \geq 3 \). In other words, any pure-state approach based on the sum of overlaps between possible final states with the time-propagated initial state of the form Eq. (8) suffers from the caveats mentioned above. The Gram-Schmidt orthonormalized basis \( \{ |\tilde{\phi}_1\rangle, \ldots, |\tilde{\phi}_n\rangle \} \) seems to be the best, yet unsatisfactory, choice for a single-particle basis.

A more convenient representation of the event probability \([8]\) is desirable. In particular, the intermediate step via the coefficients \( c_{j,k} \) is cumbersome and formal, and does not offer good physical insight. In the following, an approach based on the density-matrix formalism \([14]\), even if it seemingly presents a complication of the problem at first sight, leads to a compact form for the transition probabilities and naturally solves the exposed problems.

### III. Tensor-Permanent Approach

#### A. Event probability as expectation value

The discussion in the last section motivates us to seek a representation of event probabilities as a function of the scalar products of the single-particle mode functions, i.e. as a function of the matrix elements of the distinguishability matrix \( S \) defined in Eq. (2). Such representation emerges by expressing the measurement of the particle arrangement \( s \) by the high-dimensional operator that projects onto the space with one particle per output mode without differentiating the internal states \([15]\).

\[
\hat{P}_1 = \sum_{X_1,\ldots,X_s} \prod_{j=1}^{n} \tilde{b}_{j,X_j}^\dagger |0\rangle \langle 0| \prod_{j=1}^{n} \tilde{b}_{j,X_j},
\]

(13)
where the sum over the \( X_j \) runs over all states of a basis that span the “internal” Hilbert space, i.e. for all \( k \), \( \sum_j \langle \phi_k | X_j \rangle \langle X_j | \phi_k \rangle = 1 \). The computation of event probabilities in Ref. [33] was implicitly based on this approach, and a similar projection operator is also used in
and

The event probability \( \mathcal{P}_S(\hat{s}) \) is the expectation value of this projector,

\[
\mathcal{P}_S(\hat{s}) = \mathcal{N} \langle \Psi_{\text{fin}} | \hat{P}_1 | \Psi_{\text{fin}} \rangle, \tag{14}
\]

where the normalization factor \( \mathcal{N} = 1/(\prod_j s_j r_j!) \) becomes necessary due to our incorporation of multiply occupied input and output modes via the multiplicities of the respective rows and columns in the scattering matrix \( \hat{A} \). For convenience of notation, the normalization factor is omitted in the following by assuming – unless explicitly mentioned otherwise – that the initial and final states do not contain multiply populated modes.

The projection of the final wavefunction in the eigenspace of \( \hat{P}_1 \) is the component with precisely one particle per occupied output mode. It becomes a superposition of the particles among the modes,

\[
|\Psi_{\text{coinc}}\rangle = \sum_{\sigma \in S_n} \prod_{j=1}^n M_{\sigma,j} \hat{b}_j^\dagger |\phi_{\sigma,j}\rangle |0\rangle = \hat{P}_1 \hat{U} |\Psi_{\text{ini}}\rangle = \hat{P}_1 |\Psi_{\text{fin}}\rangle, \tag{15}
\]

i.e., the particle that was originally prepared in mode \( \sigma_j \) ends in mode \( j \), and carries its internal degree of freedom \( |\phi_{\sigma,j}\rangle \). The state \( |\Psi_{\text{coinc}}\rangle \) (besides the trivial case \( M = 1 \)) is sub-normalized, its norm yields the desired probability to find the distribution of particles \( \hat{s} \) in the output modes:

\[
\mathcal{P}_S(\hat{s}) = \langle \Psi_{\text{ini}} | \hat{U}^\dagger \hat{P}_1 \hat{U} |\Psi_{\text{ini}}\rangle = \langle \Psi_{\text{coinc}} | \Psi_{\text{coinc}} \rangle = \sum_{\sigma,\rho \in \sigma \in S_n} \prod_{j=1}^n \left( M_{\sigma,j} M_{\rho,\sigma,j}^* S_{\sigma,j} \right) \tag{17}
\]

By defining the \( n^3 \)-dimensional 3-tensor

\[
W_{k,l,j} = M_{k,j} M_{l,j} S_{k,l}, \tag{18}
\]

the event probability becomes a multi-dimensional tensor permanent \( \mathcal{P}_S(\hat{s}) = \text{perm}(W) = \sum_{\sigma,\rho \in \sigma \in S_n} \prod_{j=1}^n W_{\sigma,j,\rho,j} \), \( \tag{19} \)

which generalizes the permanent of a matrix (2-tensor). In the representations \( \tag{17} \) and \( \tag{19} \), the roles of \( M, M^* \) and \( S \) are formally equivalent; these three matrices can be permuted at will to yield different equivalent expressions:

\[
\mathcal{P}_S(\hat{s}) = \sum_{\rho \in \sigma \in S_n} \prod_{j=1}^n S_{j,\rho,j} \text{perm} \left( M^* M_{\rho,1} \right), \tag{20}
\]

\[
= \sum_{\rho \in \sigma \in S_n} \prod_{j=1}^n M_{\rho,j} \text{perm} \left( S_{1,\rho} M^* \right), \tag{21}
\]

\[
= \sum_{\rho \in \sigma \in S_n} \prod_{j=1}^n M_{\rho,j}^* \text{perm} \left( S_{1,\rho} M \right), \tag{22}
\]

where \( A_{\rho,\sigma}^* \) denotes the complex-conjugate of the matrix \( A \) with rows permuted according to \( \rho \) and columns permuted according to \( \sigma \), and \( * \) denotes the entrywise Hadamard-product.

### B. Distinguishable particles and identical bosons

Identical particles interfere perfectly, such that the sums over \( \sigma \) and \( \rho \) in Eq. \( \tag{17} \) loose their mutual dependence, and

\[
\mathcal{P}_{\text{id}}(\hat{s}) \equiv \mathcal{P}_{\text{E}}(\hat{s}) = \left( \sum_{\sigma \in \sigma \in S_n} \prod_{j=1}^n M_{\sigma,j} \right) \left( \sum_{\rho \in \sigma \in S_n} \prod_{j=1}^n M_{\rho,j} \right) = \left| \text{perm}(M) \right|^2, \tag{23}
\]

where we recover the probability for identical bosons. The simplification of \( \tag{23} \) with respect to \( \tag{19} \) arises due to the uniqueness of the final state for indistinguishable particles, i.e., the projector \( \tag{13} \) has exactly one eigenvector. Using Eq. \( \tag{20} \),

\[
\text{perm}(M) = \sum_{\sigma \in \sigma \in S_n} \text{perm} \left( M \right), \tag{24}
\]

which expresses the 1:1-relationship between single- and double-sided Feynman diagrams for coherent propagation.

For fully distinguishable particles, \( S_{j,k} = \delta_{j,k} \); one sum over all permutations in Eq. \( \tag{17} \) collapses, and

\[
\mathcal{P}_{\text{dist}}(\hat{s}) = \mathcal{P}_1(\hat{s}) = \sum_{\sigma \in \sigma \in S_n} \prod_{j=1}^n \left( M_{\sigma,j} M_{\sigma,j}^* \right) = \text{perm}(|M|^2), \tag{25}
\]

i.e., the permanent of the absolute-squared-matrix \( |M|^2 \equiv M \ast M^* \), which can be approximated efficiently thanks to the positivity of the matrix elements of \( M \ast M^* \) \( \text{[11]} \).

### C. Double-sided Feynman diagrams

Having established compact representations of the event probability \( \mathcal{P}_S(\hat{s}) \), we interpret these sums physically and visually. Eq. \( \tag{16} \) describes propagation forwards in time via \( \hat{U} \), the subsequent projection on the desired subspace via \( \hat{P}_1 \), and propagation backwards in time via \( \hat{U}^\dagger \). The sum over \( \sigma \) in Eq. \( \tag{17} \) represents all possible paths that the particles take forwards in time \( \text{[see Fig. 2(a)]} \), \( \rho \) then describes the paths backwards in time. Consequently, a particle starting in input port \( \sigma_j \) is detected in output port \( j \), to then propagate back into the initial port \( \rho_j \). The amplitudes of the processes are \( M_{\sigma,j} \) and \( M_{\rho,j}^* \), respectively, which need to
be amended further by the overlap of the internal states \( \langle \phi_{\rho_j} | \phi_{\sigma_j} \rangle = S_{\rho_j, \sigma_j} \), which explains the product of these three quantities in Eq. (17). For \( \sigma = \rho \), no bosonic exchange processes occur, which is characteristic for the classical, distinguishable contribution. All the possible processes need to be added; since the permutations \( \sigma \) and \( \rho \) describing time-forward and time-backward propagation are independent, we remain with a double-sum over \( \sigma \) and \( \rho \).

The tensor \( W_{k,l,j} \) is illustrated in Fig. 2(b): The element \( W_{k,l,j} \) contains the amplitude for a particle “starting” in \( k = \sigma_j \), being detected in \( j \) and “ending” in \( l = \rho_j \) after its time-reversed travel, each tensor element is therefore the product of the respective matrix elements of the single-particle unitary time evolution, attenuated by the scalar product of the internal state in the “initial” and “final” input mode. Each double-sided Feynman diagram corresponds to one diagonal of the 3-tensor, i.e. \( n \) cubic elements that lie on different columns for each of the three dimensions. The highlighted elements in Fig. 2(c) are precisely those corresponding to the Feynman diagram in (a).

Given this interpretation as many-particle paths, it is instructive to write the probability for partially distinguishable particles as a classical term for distinguishable particles (all paths for which the very same particles traveling forward and backward in time meet in the same output mode \( j \), i.e. \( \rho = \sigma \) in Eq. (17)), which is attenuated by exchange processes, i.e. non-classical many-particle paths,

\[
P_S(\mathcal{s}) = P_{\text{dist}}(\mathcal{s}) + \sum_{\rho \neq 1} \prod_{j=1}^{n} S_{j,\rho_j} \quad \text{perm} (M \ast M^*_{\rho,1}) \tag{26}
\]

where the number of fixed points of \( \rho, |\{k|k = \rho_k\}| \), counts the particles that do not participate in any exchange process. Interfering terms are bounded in magnitude by the classical contribution, \( P_{\text{dist}}(\mathcal{s}) \geq |\text{perm} (M \ast M^*_{\rho,1})| \), as shown in Appendix A.

D. Evaluation via Ryser’s algorithm

At first sight, Eq. (19) appears not particularly benevolent, since, instead of a sum over all \( n! \) permutations as in the matrix permanent, it contains two sums over \( n! \) entries. The computational expenses for the transition probabilities are alleviated by closely following Ryser’s algorithm [53]. Applying the inclusion-exclusion principle, we find

\[
P_S(\mathcal{s}) = \sum_{S \supseteq R \subseteq \{1, \ldots, n\}} (-1)^{|S|+|R|} \prod_{j=1}^{n} \sum_{r \in R} M_{s,j} M^*_{r,j} S_{r,s}, \tag{27}
\]

i.e. a sum over \( 2^n \) terms instead of \( n! \) as in Eq. (17). Exploiting \( W_{j,k,l} = W^*_{k,j,l} \), we eliminate approximately half of the terms,

\[
P_S(\mathcal{s}) = \sum_{S \geq R \subseteq \{1, \ldots, n\}} (-1)^{|S|+|R|} (-1)^{|S|+|R|} \times \mathbb{R} \left\{ \prod_{j=1}^{n} \sum_{r \in R} M_{s,j} M^*_{r,j} S_{r,s} \right\}, \tag{28}
\]

where \( S \geq R \) orders the subsets to avoid an evaluation of both \( (S,R) \) and \( (R,S) \). Although Eq. (28) still bears considerable computational expenses, it reduces the computational costs to a level that will allow us to numerically explore the realm of a moderate number of partially distinguishable particles in Section V, which remained unfeasible using Eq. (17).
E. Perfect suppression for partially distinguishable particles

The formalism established in Section III A allows us to explore the realm of partially distinguishable bosons and understand its peculiarities. For example, it seems tempting and rather intuitive to assume that any event \( \vec{s} \) with finite classical probability for distinguishable particles be also realized with finite probability whenever interference is not perfect, i.e.

\[
S \neq E, \mathcal{P}\text{dist}(\vec{s}) \neq 0 \Rightarrow \mathcal{P}_S(\vec{s}) \neq 0,
\]

which formalizes the intuitive idea that fully destructive interference only arises for perfectly indistinguishable particles [44] or that partial distinguishability implies imperfect visibility. A naive extrapolation of the single-particle wave-particle duality [34] to the many-body domain also seems to make such relationship plausible: Distinguishing information on the paths taken by the particles jeopardizes interference visibility.

A counter-example against conjecture (29) forces us to be careful with promoting our natural intuition based on single-particle interference to the many-particle realm: Into a setup with \( m = 9 \) modes that implements the Fourier matrix,

\[
U^{(n)}_{\text{Fourier},j,k} = \frac{1}{\sqrt{n}} e^{ij\pi x j k},
\]

we send three identical particles and one particle with varying degree of distinguishability \( x \), as described by the distinguishability matrix

\[
S = \begin{pmatrix} 1 & 1 & 1 & x \\ 1 & 1 & 1 & x \\ 1 & 1 & 1 & x \\ x & x & x & 1 \end{pmatrix}.
\]

For example, we can use three horizontally polarized photons and a fourth, vertically polarized one. The three indistinguishable (horizontally polarized) photons are prepared in a cyclically symmetric state in the input modes, the partially distinguishable photon is injected into the last mode,

\[
\vec{r}_l = (1, 0, 0, 1, 0, 0, 1, 0, 1).
\]

For the output event

\[
\vec{s}_l = (0, 1, 1, 0, 1, 0, 0, 0, 0),
\]

we combinatorially find \( \mathcal{P}\text{dist}(\vec{s}_l) = 4! / 9! \neq 0 \), while applying Eq. (17) shows that \( \vec{s}_l \) is fully suppressed for any value of \( 0 \leq x \leq 1 \), violating (29). The prevailing suppression for all values of \( x \) is surprising: \( x \neq 1 \) implies that which-path information is present, since one photon is at least partially distinguishable from the others.

Using our formalism, we understand the suppression as follows: For \( x = 1 \), the particles are fully indistinguishable and perfectly destructive interference is a consequence of the symmetries of the setup. For \( x = 0 \), we apply the suppression law for Fourier matrices [3] [29] [55] to the three indistinguishable photons. For the arrangement of indistinguishable bosons \( \vec{r} = (1, 0, 0, 1, 0, 0, 1, 0, 0) \), the following output configurations are fully suppressed:

\[
\begin{align*}
\vec{s}_1 &= (0, 1, 1, 0, 1, 0, 0, 0), \\
\vec{s}_2 &= (0, 0, 1, 0, 1, 0, 0, 1), \\
\vec{s}_3 &= (0, 1, 0, 0, 1, 0, 0, 1), \\
\vec{s}_4 &= (0, 1, 1, 0, 0, 0, 0, 1).
\end{align*}
\]

Adding a fourth, vertically polarized photon in the last input mode, the four-photon signal \( \vec{s}_l \) also remains suppressed: For any choice of the output mode of the vertically polarized photon (mode numbers 2,3,5,9), the horizontally polarized photons interfere destructively.

Formally, in Eq. (17), due to the distinguishability matrix \( S \) defined by Eq. (31), only terms with \( \sigma_4 = \rho_4 \) can be non-vanishing (the particle starting in the fourth mode needs to end in the fourth mode again, since it is distinguishable from all other particles), we therefore obtain four main contributions, visualized in Fig. 3. For each contribution, the output port of the distinguishable particle is fixed, while the three remaining particles interfere perfectly. Due to symmetry, this interference is always fully destructive, and suppresses the final state \( \vec{s}_l \).

Using Eqs. (17), (31), the event probability can be written as

\[
\mathcal{P}_S(\vec{s}_l) = \sum_{\sigma, \rho \in S_4} \prod_{j=1}^{4} M_{\sigma,j} M_{\rho,j}^* + |x|^2 \sum_{\sigma, \rho \in S_4} \prod_{j=1}^{4} M_{\sigma,j} M_{\rho,j}^*.
\]

where the first term remains free of exchange contributions that involve the fourth, possibly distinguishable particle. These exchange processes are contained in the second term, which is therefore weighted by the scalar product \( |x|^2 \). Since the event probability vanishes for \( x = 0 \) and \( x = 1 \), both sums vanish, and the probability remains 0 for every value of \( x \). Other examples can be found by a brute-force search that exploits the suppression law [5] to identify candidate instances. A systematic rule to establish such instances remains desirable.

The above example forces to abandon the intuitive idea that maximum visibility implies perfect interference: The final event \( \vec{s} \) remains strictly suppressed even though the interference capability of the system varies. This result harmonizes with the experimental data obtained in Ref. [34], which excludes a naive extrapolation of wave-particle duality to the many-body domain.
F. Mixed states

Since the mutual scalar products of different single-mode functions appear directly in the event probability Eq. (20), the latter is straightforwardly extended to mixed states by replacing scalar products by their ensemble average [50]. Assuming that the particles are uncorrelated, the process on the deterioration of interferometric signals can be used to diagnose the impact of different decoherence processes on the realization [56]. Using Eq. (17) and exchanging sums,

$$P(\hat{\sigma}_1 \ldots \hat{\sigma}_N)(\hat{s}) = \sum_{\sigma,\rho} \sum_{k_1 \ldots k_n} \left( \prod_{j=1}^{n} S[k_j, \rho_j, \sigma_j \psi_{j,k_j}] \right) \prod_{l=1}^{n} M_{\sigma_l,\rho_l}. (40)$$

We set

$$J(\sigma, \rho) = \sum_{k_1 \ldots k_n} \left( \prod_{j=1}^{n} S[k_j, \rho_j, \sigma_j \psi_{j,k_j}] \right)$$

$$= \left\{ \prod_{j=1}^{n} S[\rho_j, \sigma_j] \right\}, \quad (41)$$

for which, for the here assumed ideal detectors,

$$J(\sigma, \rho) = J(\rho^{-1}(\sigma), 1), \quad (42)$$

$$J(\sigma, 1) = J^*(\sigma^{-1}, 1). \quad (43)$$

Using Eq. (41), we recover the central result of Ref. [45]:

$$P(\hat{\sigma}_1 \ldots \hat{\sigma}_N)(\hat{s}) = \sum_{\sigma,\rho} \sum_{l=1}^{n} M_{\sigma_l,\rho_l}. (44)$$

While the $n \times n$-matrix $S$ fully describes the interference capability of a pure $n$-particle state, as it pools all $(n-1)n/2$ relevant mutual scalar products, mixed initial states require more physical parameters: Each permutation $\sigma$ gives rise to one element of $J$ in Eq. (41). Since the ensemble-average of products is not the product of ensemble-averages, e.g.,

$$\{S_{1,2}S_{2,3}\}_{\hat{\sigma}_1 \ldots \hat{\sigma}_4} \neq \{S_{1,2}\}_{\hat{\sigma}_1 \ldots \hat{\sigma}_4} \{S_{2,3}\}_{\hat{\sigma}_1 \ldots \hat{\sigma}_4}, \quad (45)$$

the matrix entries of $J$ constitute $n!$ widely independent parameters, constrained by (42), (43). The matrix $J(\sigma, \rho)$ was introduced in Ref. [45], including the effect of non-ideal detectors, which yields further independent physical parameters. For $n = 3$ pure photons and ideal detectors, $J$ coincides with the rate matrix (C2) of Ref. [48]. The rich dependence of event rates on averages of products of scalar products inherent to Eq. (44) can be used to diagnose the impact of different decoherence processes on the deterioration of interferometric signals [50].

IV. DEGREE OF DISTINGUISHABILITY

A. Permanent of the distinguishability matrix

For pure initial states, the representation of the probability as a multi-dimensional permanent [19] allows us
to identify a measure for indistinguishability: The permanent of the distinguishability matrix $S$.

The two limiting cases of identical bosons and fully distinguishable particles (Section 10.11) witness extremal values of $\text{perm}(S)$. Using $S_{j,j} = 1$ and $|S_{j,k}| \leq 1$, we find \[ 1 \leq \text{perm}(S) \leq n! \] (46)

The lower bound constitutes the permanent analogue of the Hadamard determinant inequality, it is only saturated for distinguishable particles ($S = 1$); for multiply occupied input modes, it becomes $\prod r_j! \leq \text{perm}(S)$. The upper bound is saturated if and only if all particles are fully indistinguishable ($S = E$). Besides being an unambiguous witness for the extremal cases, $\text{perm}(S)$ provides a quantitative indicator for the strength of interference, as shown in the following.

B. Bounds on the deviation from the idealized cases

Given a configuration of internal states $\{|\phi_1\rangle, \ldots, |\phi_n\rangle\}$ associated with the distinguishability matrix $S$, how strongly do the sampling probabilities under $S$ differ from those arising for fully distinguishable particles or identical bosons? Given an event $\vec{s}$, if all mutual scalar products are positive, $\forall j, k : S_{j,k} \geq 0$, it holds

$$|P_{\text{dist}}(\vec{s}) - P_S(\vec{s})| \leq P_{\text{dist}}(\vec{s}) (\text{perm}(S) - 1).$$

(47)

For general distinguishability matrices $S$,

$$|P_{\text{dist}}(\vec{s}) - P_S(\vec{s})| \leq P_{\text{dist}}(\vec{s}) (|S| - 1),$$

(48)

where the absolute value is taken entrywise. Under the assumption that $S$ is real ($\forall j, k : \Im [S_{j,k}] = 0$),

$$|P_{\text{id}}(\vec{s}) - P_S(\vec{s})| \leq P_{\text{dist}}(\vec{s}) (n! - \text{perm}(S)).$$

(49)

The proofs for these three inequalities are given in Appendix A.2. By sampling random matrices and states, we found numerical counterexamples against a naive generalization of (47) to general matrices $S$. No proof for (49) for general matrices $S$ was found, but no numerical counter-example against such generalization either. Physically, Eqs. (47,49) quantify the impact of interference contributions on the probability of individual events, i.e. $\text{perm}(S)$ quantifies the strength of bosonic exchange contributions in Eq. (26).

C. Bunching events

Bunching events of the form $\vec{s}_{\text{bunch}} = (n, 0, \ldots, 0)$ are particularly strongly affected by indistinguishability. All particles end in the same output port and interfere perfectly constructively, since all columns of the resulting scattering matrix $M$ [Eq. (1)] are identical. The inequalities (47), (49) are then saturated, even for unrestricted distinguishability matrices $S$:

$$\mathcal{P}_S(\vec{s}_{\text{bunch}}) = \frac{\text{perm}(S)}{\prod r_k} \mathcal{P}_{\text{dist}}(\vec{s}_{\text{bunch}}),$$

(50)

where multiple input mode populations are explicitly incorporated to connect our result to the full-bunching law of Refs. [50, 59], which was formulated for perfectly indistinguishable particles, and experimentally verified in Ref. [60]. In other words, the degree of bunching, i.e. the factor by which bosonic bunching boosts the probability for a bunching event with respect to distinguishable particles, is given precisely by the permanent of the distinguishability matrix, $\text{perm}(S)$, which thereby becomes a measure for bosonicness.

D. Total variation distance

We compare scattering setups in a more holistic way by analyzing the full probability distributions for all events $\vec{s}_k$ under a distinguishability matrix $S$,

$$\mathcal{P}_S = (\mathcal{P}_S(\vec{s}_0), \mathcal{P}_S(\vec{s}_1), \ldots),$$

(51)

where the ordering of events $(\vec{s}_0, \vec{s}_1, \ldots)$ is irrelevant in our context. The total variation distance (or 1-norm) between the probability distributions for identical and partially distinguishable particles is an indicator for their distinctness,

$$d_{\text{id},S} = \sum_{\vec{s}} |\vec{P}_{\text{id}}(\vec{s}) - \vec{P}_S(\vec{s})|,$$

(52)

which translates in full analogy for the variation distance between the probability distributions for distinguishable and partially distinguishable particles. Naturally,

$$d_{T,S} \equiv |\vec{P}_{\text{T}} - \vec{P}_S|_1 \leq 2,$$

(53)

for any two distinguishability matrices $T$ and $S$, and the triangle inequality holds, e.g.,

$$d_{\text{id},\text{dist}} \leq d_{\text{id},S} + d_{\text{dist},S}.$$  

(54)

By taking the sum over all final events $\vec{s}$ in Eqs. (47,49), we can state

$$S_{j,k} \geq 0 : d_{\text{id},S} \leq n! - \text{perm}(S),$$

(55)

$$\Im (S_{j,k}) = 0 : d_{\text{dist},S} \leq \text{perm}(S) - 1.$$  

(56)

We conjecture that (55) and (56) remain valid for all distinguishability matrices $S$, but we did not find a proof for these two conjectures; they are motivated by numerical evidence for random states.

The bounds can be interpreted as follows: As long as $\text{perm}(S)$ remains close to unity, interference effects are
weak and do not considerably affect the system. The approximation via the classical probability $P_{\text{dist}}(\mathbf{s})$ is then reliable. On the other hand, $\text{perm}(\mathcal{S}) \approx n!$ is tantamount to almost ideal bosonic interference. For the vast regime between these extremes, however, interference cannot be neglected, but neither can the deviation from the ideal bosonic case. In this realm, the total variation distance to both extremal distributions is large. We numerically found that, on the level of individual event probabilities, the inequalities \cite{14,18,19} are often nearly saturated [in particular, they are saturated for bunching events, Eq. (50)]; however, when summing over all events $s$, the emerging bounds \cite{55,66} are inefficient.

**V. DISTINGUISHABILITY TRANSITION**

Being equipped with the analytical tools to study the behavior of many-boson scattering – in particular, with Eq. (28) – we numerically study the behavior of few interfering bosons. Our aim is to dismiss a simple interpolation between the extreme cases, i.e. we claim that, in the vast majority of the cases, it is impossible to find a value of $\gamma$ that fulfills \cite{61}

$$\bar{P}_S = P(\gamma) \equiv (1 - \gamma)P_{\text{id}} + \gamma P_{\text{dist}}. \quad (57)$$

If a representation of the form (57) were possible, partially distinguishable Boson-Sampling would boil down to a simple mixture of classical and Boson-Sampling. To justify our claim, we compute the “closest” mixture of the form (57) for each instance defined by $\mathcal{S}$, i.e.

$$\Delta = \min_{\gamma} \|P(\gamma) - \bar{P}_S\|_1, \quad (58)$$

where $\gamma_{\text{best}}$ denotes the optimal value of $\gamma$. The quantity $\Delta$ indicates how “close” in distribution space the probability distribution $\bar{P}_S$ is to any mixture of $P_{\text{id}}$ and $P_{\text{dist}}$, as sketched in Fig. 4(a). In other words, ruling out (57) amounts to showing that $\Delta > 0$ for $1 < \text{perm}(\mathcal{S}) < n$.

**A. Canonical transition**

There are many different ways to proceed from distinguishable particles ($S = 1$) to indistinguishable particles ($S = E$) in an experiment \cite{11}; we start by studying a smooth parameterization that interpolates between the two limits,

$$S_{j,k} = x \text{ for all } j \neq k, \quad (59)$$

i.e. the scalar product between any two single-particle wavefunctions is $x$; the permanent of $\mathcal{S}$ becomes an $n$th order polynomial in $x$. The matrix $\mathcal{S}$ is realized, e.g., in an $n + 1$-dimensional internal Hilbert space in which the single-particle wavefunctions are given by

$$|\phi_k\rangle = (\sqrt{x}, 0, \ldots, 0, \sqrt{1-x}, 0, \ldots, 0)_{k=1}^{n-k-1}. \quad (60)$$

in some basis. We explore the transition between bosons and distinguishable particles by varying $x$ in Fig. 4(b,c,d). To compare various particle numbers, we show $\Delta$ and the total variation distances $d_{\text{dist},S}$, $d_{\text{id},S}$ as a function of the normalized permanent, $0 \leq \ln(\text{perm}(S))/\ln(n!) \leq 1$. A monotonic relationship between the normalized permanent and the total variation distances emerges: The stronger the interference, the closer we come to the probability distribution for bosons [Fig. (d)], and detach us from the one for distinguishable particles [Fig. (c)]. The former shows a behavior that depends of the total particle number $n$, for the latter different particle numbers only divide up for large interference, which may, however, be an artifact of our ad-hoc choice of normalization for $\text{perm}(S)$. The monotonic relationship between the total variation distance and the degree of interference exhibited in Fig. 4(c,d) is, however, not realized on the level of individual events, which often exhibit intricate structures \cite{3,5,42,43,63}. Unlike what the data in the two panels (c,d) may suggest at first sight, the probability distribution for partially distinguishable bosons $\bar{P}_S$ does not lie on the direct line between the extremes $P_{\text{id}}$ and $P_{\text{dist}}$, which is witnessed by the non-vanishing values of $\Delta$ in panel (b). The trend to explore an intricate path in the space of probability distributions far away from any mixture $P(\gamma)$ becomes more pronounced for larger numbers of particles.

**FIG. 4:** (a) Location of $\bar{P}_S$, $P_{\text{id}}$ and $P_{\text{dist}}$ in the high-dimensional space of probability distributions. The value of $\Delta$ indicates the distance (1-norm) to the closest mixture $P(\gamma)$ on the direct line between $P_{\text{id}}$ and $P_{\text{dist}}$. (b) Minimal total variation distance $\Delta$ between $\bar{P}_S$ and a mixture of distinguishable and indistinguishable bosons. (c,d) Total variation distance between $\bar{P}_S$ and the probability distribution of distinguishable particles and identical bosons, respectively. We parametrize the many-body state with $n = 3, \ldots, 7$ according to Eq. (59) and show the variation distance as a function of the normalized permanent of $\mathcal{S}$, $0 \leq \ln(\text{perm}(S))/\ln(n!) \leq 1$. The error bars show one standard deviation, we have sampled 160 unitary matrices for each $n$ and estimated $\Delta$ by evaluating the probabilities of up to 100 randomly chosen events for each configuration of $x$ and $U$. The number of modes fulfills $m = 2n$, 15 equidistant values of $0 \leq x \leq 1$ were used.
To give a more complete picture of the many-body distinguishability transition, we generate instances of $(\gamma_{\text{best}}, \Delta)$ for random choices of $S$ as follows: For a chosen dimension $2 \leq D \leq n$, the $n$ internal states $|\phi_1\rangle, \ldots, |\phi_n\rangle$ for the $n$ incoming particles are uniformly randomly chosen. The typical scalar products depend on $D$: There cannot be $D + 1$ fully distinguishable particles in a $D$-dimensional space.

Our numerical results for randomly chosen unitary matrices of dimensions $m = 2n$ are illustrated in Fig. 4. We sampled 10000, 5000 and 2000 random configurations of distinguishability $S$ for $n = 3, 4, 5$, respectively, for $D = 2, \ldots, n$. The color code indicates the degree of interference, $\text{perm}(S)$. Large values of $\text{perm}(S)$ lead to small values of $\gamma_{\text{best}}$, i.e. the more the particles interfere, the closer we find ourselves to the ideal situation of indistinguishable bosons. Small values of $\text{perm}(S)$ are associated to $\gamma_{\text{best}} \approx 1$ and weak interference. The total variation distance between distinguishable and indistinguishable particles is $d_{\text{dist}} = 0.70, 0.78, 0.88$ for $n = 3, 4, 5$, respectively, $\Delta$ often takes comparable values. Our parameterization (59) typically leads to smaller values of $\Delta$ for a given $\gamma_{\text{best}}$ than for randomly chosen states: The smooth parameterization ensures that all events are equally strongly affected by partial distinguishability, keeping the probability distribution closer to a mixture of the extremal cases.

A particularly sharp difference between distinguishable and identical particles arises for the Fourier-matrix [49]. For a given setting of $n$, $m = 2n$ and a cyclically symmetric initial state of the form $|\varphi\rangle = (1, 0, 0, \ldots, 1, 0, 0, \ldots)$, the total variation distance between distinguishable and identical particles is significantly larger than for randomly chosen matrices: Due to the Fourier suppression law [49, 55], a fraction of approximately $(n - 1)/n$ of all events is fully suppressed, strongly enhancing the remaining $1/n$ of events. The expected variation distance is, therefore, $2(n - 1)/n$, an estimate that Fig. 6 confirms empirically. Fourier matrices also lead to particularly large values of $\Delta$ and pronounced edges of the scatter-plot in Fig. 7.

### B. Random states

A particularly sharp difference between distinguishable and identical particles arises for the Fourier-matrix [49]. For a given setting of $n$, $m = 2n$ and a cyclically symmetric initial state of the form $|\varphi\rangle = (1, 0, 0, \ldots, 1, 0, 0, \ldots)$, the total variation distance between distinguishable and identical particles is significantly larger than for randomly chosen matrices: Due to the Fourier suppression law [49, 55], a fraction of approximately $(n - 1)/n$ of all events is fully suppressed, strongly enhancing the remaining $1/n$ of events. The expected variation distance is, therefore, $2(n - 1)/n$, an estimate that Fig. 6 confirms empirically. Fourier matrices also lead to particularly large values of $\Delta$ and pronounced edges of the scatter-plot in Fig. 7.

### D. Absence of interpolating transitions

Is it ever possible to parametrize the transition between indistinguishable and distinguishable particles such that we can write $\hat{P}_S$ in the intuitive form (57)? Here, we argue that, beyond a trivial case, such construction is unlikely. The following mixed many-particles state leads to (57):

$$\rho = \gamma |0\rangle \langle 0|^n + \gamma \otimes_{j=1}^n |j\rangle \langle j|,$$

where $\langle j|k\rangle = \delta_{j,k}$ and we refer to the $n + 1$ internal states of the particles. Eq. (61) describes a probabilistic mechanism that produces a state of $n$ indistinguishable particles with probability $\gamma$ and a state of $n$ distinguishable
particles otherwise. The particles in this mixed state are strongly classically correlated: They are prepared either all in the same state or all in different states.

For uncorrelated pure states, the condition for a parameterization of the form \( \mathcal{P}_{\Sigma}(\vec{s}) \) reads

\[
\mathcal{P}_{\Sigma}(\vec{s}) = \mathcal{P}_{\text{dist}}(\vec{s}) + \sum_{\sigma \neq 1} \left( \prod_{k=1}^{n} S_{k,\sigma_k} \right) \text{perm}(M \ast M_{\sigma,1})
\]

\[
= \mathcal{P}_{\text{dist}}(\vec{s}) + (1 - \gamma) \sum_{\sigma \neq 1} \text{perm}(M \ast M_{\sigma,1}),
\]

which has to hold for all events \( \vec{s} \) (remember that the matrix \( M \) depends on the output state \( \vec{s} \) in Eq. (1)). For a fixed unitary matrix, the number of events \( \vec{s} \) is much larger than the number of adjustable parameters \( n(n - 1)/2 \), such that Eq. (62) is heavily overdetermined and a solution impossible in the vast majority of the cases.

It is difficult to relate the contributions of different permutations \( \sigma \) to each other. A neat relationship may be useful to devise a parametrization: Since the sum of all event probabilities is unity,

\[
\sum_{\sigma \neq 1} \sum_{\vec{s}} \text{perm}(M \ast M_{\sigma,1}^*) = 0,
\]

and the latter holds for all distinguishability matrices \( \Sigma \), it is valid for each permutation \( \sigma \), such that

\[
\forall \sigma \neq 1 : \sum_{\vec{s}} \text{perm}(M \ast M_{\sigma,1}^*) = 0.
\]

Intuitively speaking, each exchange process defined by \( \sigma \neq 1 \) yields positive and negative interference contributions, which cancel in total when considering all possible events.

It remains open whether a non-trivial parametrization exists for mixed uncorrelated states of the form [36]: Since the ensemble-averaged scalar products take many different independent values (Section III F), an ingenious parametrization that achieves (62) is not excluded.

VI. CONCLUSIONS AND OUTLOOK

The treatment of partially distinguishable particles used implicitly in Ref. [35], formalized in Ref. [45] and taken further in this article overcomes the issues enumerated in Section II E. Since our central Eq. (17) directly contains the mutual scalar products of the internal states of the interfering particles, there is no dependence on a choice of single-particle basis [5, 44]. Our approach is readily interpreted and visualized by double-sided Feynman diagrams (Fig. 2), the emerging multi-dimensional permanent [19] provides an intuitive and manageable way to deal with the imperfect interference of partially distinguishable bosons.

Simulating Boson-Sampling is classically hard, even if only an approximation is sought, whereas sampling of distinguishable particles can be done efficiently. From this perspective, the current status is unsatisfactory: It would be counter-intuitive if the complexity for the intermediate case treated here should explode while the physical transition between the extremes arises naturally. We cannot conclusively answer our initial question on the computational hardness of the sampling problem in the partially distinguishable realm, but, based on our discussion in Section V, we refuted any naive interpolation between the limiting cases and presented counter-intuitive phenomena such as the prevalence of fully destructive interference for partially distinguishable particles (Section III E).

Even though the distinguishability transition is not mediated by a single parameter and can take many different forms depending on the actual path taken from \( \Sigma = 1 \) to \( \Sigma = \text{E} \), a measure for interference capability was found: the permanent of the distinguishability matrix \( \Sigma \). Not only does it yield the simple bounds [17], [48], and [49] on the deviation to the extremal cases, but it can be read off experimentally as the degree of bunching [Eq. (50)]. The latter result is connected with the recent observation that Boson-Sampling with thermal states is related to the permanent of a positive semidefinite hermitian matrix [64]. In our case, the matrix \( \Sigma \) defined in Eq. (2) encodes the mutual distinguishability of the internal states of the injected bosons, while in Ref. [64], the pertinent hermitian matrix is built of elements of the scattering matrix \( U \). The permanent of a positive semidefinite hermitian matrix is not a hard computational problem, since one can conceive efficient classical approximations [64], consistent with the existence of strong bounds [65, 66].

The role of the permanent is strengthened as an ubiquitous and essential function in many-boson interference,
generalizing the classical and bosonic cases. To compare different experiments and particle numbers, it remains to find an sensible way to scale the range of $\text{perm}(S)$, $[1, n!]$, such that it quantitatively reflects the degree of interference; one possibility is our normalization adopted in Fig. 4. Given that the bounds (47) and (19) are formulated under strong assumptions on the structure of $S$, it is also desirable to find a generalization to unrestricted distinguishability matrices $S$, as well as an extension to mixed states. Although Eq. (28) is more benevolent than Eq. (8), we suspect that there are more efficient ways to evaluate (17) than our adaptation of Ryser’s algorithm: Even in the most general case, the multi-dimensional permanent (19) is not applied to a general 3-tensor with $n^3$ independent elements, but to a tensor fixed by two complex matrices through Eq. (18). A way to exploit this symmetry in the computation of probabilities would significantly alleviate the computational expenses related to partially distinguishable bosons.

The sampling problem possesses well-understood limiting cases: semi-classical sampling in the many-particle limit $n \gg m$ [33, 34], classical sampling for distinguishable particles, Fourier-sampling for structured scattering matrices [3, 32] and computationally hard Boson-Sampling [2], possibly realized with an input beyond multi-mode Fock-states [23–25]. These discrete cases constitute the corners of the high-dimensional and widely unexplored phase diagram of sampling complexity, whose precise demarkation from a physical and computer-science perspective constitutes an ambitious desideratum. Given the fruitful interplay of computational complexity theory and physics in the understanding of many-particle interference so far, it is not unrealistic to hope for future further synergy and insight [67].

Acknowledgements

The author thanks Scott Aaronson, Clemens Gneiting, Steven Kolthammer, Hyang-Tag Lim, Benjamin Metcalf, Young-Sik Ra, Si-Hui Tan and Ian Walmsley for inspiring discussions, Hubert de Guise, Klaus Mølmer and Valery Shchesnovich for very valuable feedback on the manuscript, and the Villum Foundation and the Danish Council for Independent Research for financial support.

Appendix A: Proofs and useful relations

1. Maximizing permutation

The most important contribution to the sum (20) is the classical event probability:

$$\text{max}_σ |\text{perm}(M * M_{σ,1}^*)| = \text{perm}(M * M_{1,1}^*) = \mathcal{P}_{\text{dist}}(\vec{s})$$  \hspace{1cm} (A1)

To see this, set $m_ρ = \prod_j M_{j,ρ_j}$ and write

$$\text{perm}(M * M_{σ,1}^*) = \sum_{ρ∈S_n} m_ρ m_ρ^*(σ),$$  \hspace{1cm} (A2)

which is maximized for $σ = 1$.

2. Upper bound on probability difference

We first prove Eq. (47), where we explicitly require $S_{j,κ} ≥ 0$ for all $j, κ$:

$$|P_{\text{dist}}(\vec{s}) − P_S(\vec{s})| \leq \sum_{σ∈S_n,σ\neq1} |\text{perm}(M * M_{σ,1}^*) \prod_{j=1}^n S_{j,σ_j}|$$

$$\leq \sum_{σ∈S_n,σ\neq1} \text{max}_ρ |\text{perm}(M * M_{ρ,1}^*) \prod_{j=1}^n S_{j,σ_j}|$$

$$\leq \text{max}_ρ |\text{perm}(M * M_{ρ,1}^*) \prod_{σ∈S_n,σ\neq1} \sum_{j=1}^n S_{j,σ_j}|$$

$$\leq \text{max}_ρ |\text{perm}(S) − 1| \cdot \mathcal{P}_{\text{dist}}(\vec{s})$$  \hspace{1cm} (A3)

Breaking the assumption $S_{j,κ} ≥ 0$ invalidates the inequality. Considering $\text{perm}(S)$ instead, we recover inequality (48).

Similarly, one shows (55) for distinguishability matrices fulfilling $S_{j,κ} ∈ \mathbb{R}$:

$$|P_{\text{id}}(\vec{s}) − P_S(\vec{s})| \leq \sum_{σ∈S_n} |\text{perm}(M * M_{σ,1}^*) \prod_{j=1}^n S_{j,σ_j}|$$

$$\leq \text{max}_ρ |\text{perm}(M * M_{ρ,1}^*) \prod_{σ∈S_n} \sum_{j=1}^n S_{j,σ_j}|$$

$$\leq \text{max}_ρ |\text{perm}(S) − 1| \cdot \mathcal{P}_{\text{dist}}(\vec{s}) (n! − \text{perm}(S))$$  \hspace{1cm} (A4)

For general matrices $S$, we have not found any instance that violates the generalization of inequality (A1), but the last step of our proof above breaks down.
