Psoriasis is a multi-factorial disease with various clinical manifestations. We present a case of unilateral psoriasis associated with ipsilateral lymphedema that developed after mastectomy for breast cancer. A 42-year-old Korean woman was referred to our clinic with a 1-month history of multiple erythematous scaly patches on the right arm, back, and breast and was diagnosed with psoriasis by a skin biopsy. Three years previously, she had been diagnosed with breast cancer (T1N2), underwent a right quadrantectomy and axillary lymph node dissection, and completed adjuvant chemotherapy followed by high-dose adjuvant radiotherapy. She had started rehabilitation therapy on the right arm for secondary lymphedema 30 months previously. Because of the long interval between radiation and psoriasis, we speculated that changes in the local milieu caused by the lymphedema might be a causative factor. We hereby report a rare case of unilateral psoriasis following post-mastectomy lymphedema. (Ann Dermatol 23(S3) S303 ~ S305, 2011)

INTRODUCTION

Psoriasis is an inflammatory disease with various clinical manifestations but it usually shows a symmetric distribution. Several cases with unilateral distribution have been reported under various conditions such as the postoperative state of neurosurgery1, a Koebner reaction after radiotherapy2, and in association with inflammatory linear verrucous epidermal nevus3, and so on. We report the case of a 42-year-old woman, who presented with unilateral psoriasis that developed after an ipsilateral mastectomy for breast cancer.

CASE REPORT

A 42-year-old woman with a known history of breast cancer was referred to our clinic with a 1-month history of multiple erythematous scaly patches on the right side of the arm, breast, and back (Fig. 1A). The lesions on the right arm appeared first and spread serially to the right breast and back during the next month. Three years previously she had been diagnosed with infiltrating ductal carcinoma of the right breast and underwent a right breast-conserving mastectomy and axillary lymph node dissection. Tumor stage was determined pathologically to be T1N2(4/10)M0. Three weeks later, she started adjuvant chemotherapy with four cycles of doxorubicin and cyclophosphamide, followed by four cycles of docetaxel for 5 months. After 1 month, she underwent radiation therapy to the whole right breast with a dose of 50.4 Gy and a boost to the tumor bed with a dose of 9 Gy in 33 total fractions. After radiation therapy was completed, she started rehabilitation therapy with complete decongestive therapy on the right arm for the secondary lymphedema. About 2 year later, she presented with a skin eruption. A physical examination showed multiple, oval to round...
Fig. 1. (A) Multiple erythematous patches with few scales on the right arm, breast, and back. (B) Near clearance state of the lesions on the right breast and back with post-inflammatory hyperpigmentation after narrow band-ultraviolet B treatment and application of Diavobet® cream for 4 weeks.

Fig. 2. Histological examination of the right breast revealed an irregular acanthosis with rete ridge elongation, parakeratotic mounds with focal hypogranulosis, and perivascular lymphocytic infiltration into the upper dermis (H&E, ×200).

DISCUSSION

Psoriasis is a multi-factorial disease with various clinical patterns. Linear or unilateral psoriasis is a very rare clinical form of skin presentation. The psoriatic lesion commonly occurs as a linear lesion on the limbs but may also be limited to a dermatome on the trunk4. This particular manifestation usually presents related to several conditions, such as a post-nerve injury state1,5 or as a Koebner2,6 or reverse Koebner reaction7 after radiotherapy, in association with inflammatory skin disease3,8.

In our case, several factors were considered the cause of the psoriasis. First, the Koebner phenomenon after radiation therapy could be an etiological factor. However, because of the long interval between radiation and psoriasis, it was difficult to consider the unilateral distribution as a Koebner phenomenon. The Koebner phenomenon usually occurs 7~14 days after injury, but our patient had a 2-year interval between the skin eruption and radiation therapy. Some chemotherapeutic agents9 could induce a psoriasiform eruption. However, our patient had no history of medication that could exacerbate or trigger psoriasis, and the time interval was long after the previous chemotherapy. Paraneoplastic dermatosis10 was also not considered a cause of the skin eruption, because there was no evidence of breast cancer recurrence. Because the previous factors were unsatisfactory as a cause for the unilateral psoriasis, we speculated that the prolonged lymphedema could have led to the development of the psoriasis. Tissue biology changes occur in a state of chronic lymphatic edema, including increases in cytokines, growth factors, and cutaneous structures11. Hyperkeratosis, spongiosis, and edema in the epidermis and elongation of the dermal papillae are observed. In addition, there is remarkable cell infiltration with fibroblasts, histiocytes, and...
neutrophils in the dermis. Although no case associated with chronic lymphedema has been described, such changes could cause a change in the local tissue milieu and result in an ipsilateral, unilateral distribution. Alternatively, mild damage to the postsurgical peripheral nervous system\textsuperscript{1,5} could have resulted in the unilateral distribution of psoriasis.

We hereby report a rare case of unilateral psoriasis associated with ipsilateral, post-mastectomy lymphedema.
