Introduction

The barn owl (BO, *Tyto alba*, family Tytonidae) and collared scops owl (CSO, *Otus lettia*, family Strigidae) are common nocturnal raptors throughout Thailand. Blood samples from 23 adult BOs and 14 CSOs were collected and processed for complete blood cell counts and parasite morphological examinations. Two *Haemoproteus*-positive samples were processed for ultrastructural observation. Polymerase chain reaction (PCR) analysis for a partial cytochrome *b* gene (cyt *b*) from *Haemoproteus* was performed in all samples. *Haemoproteus* presence detected by light microscopy was lower than that detected by PCR (30.4% and 34.8%, respectively, in BO; and 50.0% and 78.6%, respectively, in CSO). Comparative hematology revealed that *Haemoproteus*-positive BOs had higher mean cell hemoglobin concentration, total leukocyte, absolute heterophil, basophil, and monocyte counts than *Haemoproteus*-negative BOs, but no significant differences between *Haemoproteus*-negative and -positive CSOs. Monocyte ultrastructure analysis revealed a role in the elimination of gametocytes. Morphologically, the *Haemoproteus* in 3 BOs and 6 CSOs were identified as *H. noctuae*, while that in 1 CSO was identified as *H. syrii*. Phylogenetic analysis indicated the *Haemoproteus* spp. in 8 BOs and 7 CSOs were not closely related to *H. noctuae* or *H. syrii*, and the cyt *b* of 2 CSOs was that of *H. syrii*. These results should be useful for study of *Haemoproteus*.

These results should be useful for study of *Haemoproteus*.

The barn owl (BO, *Tyto alba*, family Tytonidae) and collared scops owl (CSO, *Otus lettia*, family Strigidae) are common nocturnal raptors of the order Strigiformes and are common in all parts of Thailand [7]. Since 1992, both owl species have been protected under the Wildlife Protection and Preservation Law. BOs were the most common species of raptors submitted to the Kasetsart University Raptor Rehabilitation Unit (KURRU) from 2008 to 2011 [14], and the BO is listed as a near-threatened species in the Red Data of Thailand. Although the hematologic values in BO have been reported [1], little is known about the hemoparasites of these two owl species in Thailand.

Avian blood parasites cause infections of concern in wild birds. *Haemoproteus* spp., a vector-borne parasite, is transmitted by hippoboscid flies and biting midges [26]. *Haemoproteus* spp. often does not result in clinical disease; however, hemolytic anemia resulting in severe anemia in Harris hawks [19] and juvenile snowy owls has been reported [20]. These hemoparasites can cause disease in pigeons and quails, but low pathogenicity has been observed in other avian species [5]. Nested cytochrome *b* (cyt *b*) polymerase chain reaction (PCR) analysis is widely used to detect hemosporidian blood parasites in the peripheral blood of birds [4,9,10,28], and molecular studies have described a parasite diversity remarkably higher than previously expected [29]. The cyt *b* sequences of only three species of *Haemoproteus* (H. *noctuae*, H. *syrii*, and H. *ilanpapernai* [12,26]) that infect owls in the order Strigiformes have been reported in the GenBank database (National Center for Biotechnology Information, USA) [4,12,13]. Paperna et al. [21] reported *H. noctuae* morphology in brown hawk owls (*Ninox scutulata*) and collared owlets (*Glaucidium brodiei*) from Malaysia and *H. syrii* morphology in *N. scutulata* and spotted wood owls (*Strix seloputo*) from Singapore. However, there were no reports describing *Haemoproteus* infections in BO and CSO from Thailand, even in the Asia survey [11,21].

The purposes of this study were to determine the hematologic, morphometric, and phylogenetic relationships, as well as the ultrastructural characteristics, of *Haemoproteus* infecting the BO and CSO submitted to KURRU. The hematozoa infections...
based on blood smear examination and PCR screening were also compared.

Materials and Methods

Ethics statement

The present study was approved by the Institutional Laboratory Animal Care and Use Committee of Kasetsart University of Thailand (protocol No. ACKU 01560).

Sample collection, hematology, and morphological study

Blood samples were collected from 23 adult BOs (10 males and 13 females) and 14 CSOs (6 males and 8 females) at KURRU from May 2013 to February 2016. The owls were clinically healthy, with a good body score, and were prepared for release from KURRU. For sample collection, each owl was physically restrained by using a net, and 1 mL of blood was collected from the jugular or ulnar vein into an ethylenediaminetetraacetic acid (EDTA)-containing tube, and the sample was immediately stored at 4°C.

Blood smears were immediately prepared, air-dried, and stained with Wright’s stain (an in-house preparation using Wright eosin methylene blue and Giemsa’s azur eosin methylene blue; Merck KGaA, Germany) for grading of blood parasite infection and morphologic evaluation of red blood cells (RBCs). Each smear was examined for 10 min at ×400 magnification to detect blood parasite infection. Infection intensity was estimated as a percentage by counting the number of parasites per 10,000 RBCs at high magnification (×1,000). Leukocyte differential counts were based on an average count of 200 cells by two veterinary hematologists. Thrombocytes per 100 white blood cells (WBCs; expressed as thrombocyte percentage) were also counted.

Complete blood cell counts were obtained by using previously described methods [23]. Briefly, packed cell volumes (PCV) were determined by using a microhematocrit centrifuge at 10,000 × g for 5 min. Total RBC and WBC counts were determined manually by using a counting chamber after the blood had been diluted 200 times with Natt and Herrick’s solution, as described previously [5,23]. A corrected WBC count was calculated by applying the following formula: WBC × 100/(100 + thrombocyte percentage). The hemoglobin concentration was determined by the cyanmethemoglobin method, in which free RBC nuclei were removed by centrifugation before reading the absorbance. The mean cell volume (MCV) and mean cell hemoglobin concentration (MCHC) were calculated from the PCV, hemoglobin concentration, and RBC count. Reticulocyte counts (aggregate and punctate) were determined by staining with new methylene blue and using a wet preparation. Total protein and fibrinogen concentrations were determined by using a refractometer (Atago, Japan) and the heat precipitation method for fibrinogen.

A BX53 light microscope (Olympus, Japan) equipped with a DP73 digital camera and cellSens Standard imaging software (ver. 01.07; Olympus) was used to examine the stained smears. Morphometry (width, length, area, number of pigment granules, and nuclear displacement ratio [NDR] [2]) of 16 to 20 macrogametocytes was undertaken in each owl determined to be positive for Haemoproteus by light microscopy. The NDR was calculated according to the following formula: NDR = 2x/(x + y), where x and y were the width between the nucleus and cell membrane with and without the gametocyte [2]. Morphometry (width, length, area, perimeter, and diameter) of both Haemoproteus-infected and non-Haemoproteus-infected RBCs was performed in 20 to 131 randomly selected RBCs.

Statistical analysis

The hematological results are presented as mean ± SE values. The Mann-Whitney U test was used to determine the statistical significance of differences between Haemoproteus-negative and -positive owls. Extreme morphometric values were assessed by using scatter plots before exclusion from the data. The data were examined for the presence of a normal distribution by using the Shapiro-Wilk W test and the Kolmogorov-Smirnov test. Descriptive statistics (mean and SD) were used to describe the data. The length and width hematozoa data that had a normal distribution were compared with previously reported data (means and SD) [21] by using a two-sample t-test. The effect of macrogametocytes on RBC parameters was assessed by using one-way analysis of variance (ANOVA). All statistical analyses were performed by using NCSS 2007 (NCSS, USA).

Ultrastructural study

The EDTA-treated blood samples from 1 BO (KU71) and 1 CSO (KU222) were processed for transmission electron microscopy by using standard methods, as previously described [24]. Briefly, buffy coats were fixed with 2.5% glutaraldehyde, post-fixed in 1% osmium tetroxide, dehydrated in an acetone series, and embedded in Spurr’s epoxy resin. Ultrathin sections stained with uranyl acetate and lead citrate were observed by using an HT7700 transmission electron microscope (Hitachi, Japan).

Molecular study

All EDTA blood samples were processed for genomic DNA extraction by using a Blood Genomic DNA Extraction mini-kit (Favorprep, Taiwan). Genomic DNA from each blood sample was analyzed by using nested PCR to amplify a fragment of the cyt6 gene from Haemoproteus spp., as described previously [6,10]. Briefly, specific primers designated as HaemNF and HaemNR2 were used for primary PCR amplification by using recombinant Taq DNA polymerase (Invitrogen, USA). The amplified primary PCR product was used as the template for nested PCR. The amplicons were stained with GelStar (Lonz
Results

Hematology, light microscopy, and ultrastructural morphology

*Haemoproteus* gametocytes were found in blood smears of 7 BOs (30.4%; panels A and B in Fig. 1) and 7 CSOs (50%; panels C–F in Fig. 1). In general, less than 0.1% infected RBCs were found, except for CSO KU222, which had a 2% RBC infection rate (panel E in Fig. 1). Hematology revealed significantly lower MCHC, total leukocyte, absolute heterophil, basophil, and monocyte counts in *Haemoproteus*-negative than in *Haemoproteus*-positive BOs (Table 1). In contrast, for CSOs, there were no significant differences detected between the *Haemoproteus*-negative and -positive owls (Table 2). BOs had higher MCV than those of CSOs (Tables 1 and 2).

The *Haemoproteus* gametocytes displayed halteridial (almost completely encircling the nucleus of infected RBCs; panels A and C in Fig. 1) or banana shapes (panels B and F in Fig. 1). Some mature gametocytes (CSO KU181) completely encircled the nuclei of the infected RBCs (circumnuclear; panel D in Fig. 1) but did not laterally displace any nuclei. Extra-erythrocyte rounded gametocytes (panel E in Fig. 1) were frequently observed in all owls except CSO KU127, which showed only banana-shaped gametocytes (panel F in Fig. 1). The cytoplasm of the gametocytes contained grouped or scattered yellow-brown- to dark-pigmented granules (Fig. 1), with different average

Data are presented as mean ± SD. NDR = 2x/(x + y), where x and y were the width between the nucleus and cell membrane with and without the gametocyte. NDR, nuclear displacement ratio; ND, no data. *Significant difference from H. syrnii in spotted wood owl at p < 0.05.

for H. noctuae [21] (Table 3). The macrogametocytes of Haemoproteus in CSO KU127 were longer but slightly narrower than that in the reference data (Table 4), and molecular study revealed that they were closely related to H. syrnii obtained from spotted wood owls [21] (Figs. 3 and 4).

In BO individuals, H. noctuae halteridial gametocyte-infected RBCs showed significantly greater length, width, and area than those of non-infected RBCs, whereas the nuclei length in infected RBCs was significantly shorter than that in non-infected RBCs (Table 5). The nuclei of circumnuclear gametocyte-infected RBCs were smaller in length and area, but the length and area of the infected RBCs were larger than those of non-infected RBCs (Table 5). The infected nuclei were more condensed than non-infected nuclei (Fig. 1).

In CSOs, H. noctuae-infected RBCs were significantly greater in length and area, but smaller in nuclei length and area of the nucleus than those of non-infected RBCs (Table 5). Only the area of H. syrnii-infected RBCs was significantly lesser than that in non-infected RBCs (Table 5). None of the Haemoproteus gametocytes displaced the host nuclei (NDR > 0.7). The non-infected RBCs in BO had a greater area than those in CSO (Table 5), which correlated with the larger MCV in BO (Tables 1 and 2).

Molecular study

We detected fewer Haemoproteus infections by using light microscopy than by PCR analysis (30.4% vs. 34.8% in BO and 50.0% vs. 78.6% in CSO). Samples from 1 BO and 4 CSOs that were PCR-positive but microscopy-negative were re-examined microscopically by two hematologists screening two entire blood smears from each individual owl. They were all confirmed to be Haemoproteus-negative.

The phylogenetic tree of 19 partial cyt b gene sequences from 8 BOs and 11 CSOs (Fig. 3) revealed that all partial Haemoproteus cyt b genes in this study were grouped in a monophyletic group with a 94% bootstrap value. The Haemoproteus isolates from 8 BOs (KU71, -86, -112, -120, -132, -200, -202, and -203) and 4 CSOs (KU284, -163, -248, and -250) were similar to H. noctuae hCIRCUM01 (KP794612) isolated from Asio otus in Russia (96.2%). The Haemoproteus isolates from 5 CSOs (KU181, -222, -226, -259, and -318) were very similar to H. noctuae hCIRCUM01, with 98% similarity. H. noctuae (KP794612) and H. syrnii (KP794611) formed a small clade, suggesting that they were closely related. Similarly, 2 H. syrnii (KF279523 and EF607209) were observed to be closely related.

The Haemoproteus isolate from KU234 CSO was similar (96.5%) to H. syrnii (EF607290; Fig. 3), whereas the Haemoproteus in KU127 CSO was identical to H. syrnii in tawny owls, Strix aluco, from Russia (KP794611), and was closely related (99.4%) to H. syrnii isolated from Eurasian scops owls, Otus scops, in Bulgaria (KP451480).
**Haemoproteus** isolates in our study formed one large cluster and were different from those infecting other avian species (isolated from Passeriformes, Suliformes, and Columbiformes birds), which showed that the genetic distance ranged from 3.8% to 13.6%. The *Haemoproteus majoris* in passerine birds (AF254972 and AF254977) were distanced from the studied *Haemoproteus*, with 93.9% to 96.2% genetic similarity (Fig. 3). However, the types of *Haemoproteus* described in our study were all more closely related to each other than to *H. majoris*.

Comparison of amino acid sequences of the cyt b protein revealed specific consensus residues for the studied *Haemoproteus* groups (Fig. 4). Alanine was conserved at residue 1288 of *Haemoproteus* in KU234 CSO. Methionine was located at residue 1288 of the *Haemoproteus* isolates from the other 5 CSOs (KU181, -222, -226, -318, and -259). Two isoleucines and 1 threonine were conserved at residues 1264, 1281, and 1282 of the *Haemoproteus* infecting 8 BOs (KU71, -86, -112, -120, -132, -200, -202, and -203) and 4 CSOs (KU 163, -248, -250, and -284).

## Discussion

To our knowledge, this is the first study to record *Haemoproteus* in BO and CSO in Thailand based on optical microscopy and molecular studies. The higher MCHC in *Haemoproteus*-positive BOs may due to the hemolysis of infected RBCs, but this result was not observed in CSOs; that difference might be due to the low number (only 3 owls) of *Haemoproteus*-negative owls compared to 11 *Haemoproteus*-positive CSOs. The higher total leukocyte, absolute heterophil, basophil, and monocyte counts in *Haemoproteus*-positive BOs may be due to active *Haemoproteus* elimination functions in this species of owl. *Haemoproteus* is generally considered nonpathogenic in raptors; however, there have been reports of fatalities in owls [22]. The increased leukocyte counts in BO supports the greater pathogenicity of *Haemoproteus*. The erythrocyte parameters (PCV, MCV, and MCHC) in *Haemoproteus*-negative BO in the present study were less than those reported from BO (n = 21) in the USA [1], which might be...
due to different climates and/or different water intake of the owls.

Both halteridial and circumnuclear gametocyte-infected RBCs were larger than non-infected RBCs due to loading of the parasite in the cytoplasm of the RBCs. The reduction in length of nuclei of infected RBCs in both BOs and CSOs may be a pathologic effect in which infected nuclei are more condensed than non-infected nuclei. The lengths of *Haemoproteus* halteridial gametocytes from CSOs were smaller than those from BOs, although the phylogenetic analysis revealed that they were the same *Haemoproteus* species. This might be due to the larger size of RBCs in BOs than in CSOs. The shorter width but longer length of *H. syrii* gametocytes in KU127 CSO compared to that in spotted wood owls [21] might also be due to a RBC size

---

Fig. 4. Comparison of partial amino acid sequences of the cytochrome b (cyt b) region inferred from previous reports and our nucleotide sequences obtained from *Haemoproteus*-infected owls. These amino acids were located on 1259–1373 residues of cyt b protein compared with the complete genome of cyt b gene of *Haemoproteus columbae* (NC 012448). *Haemoproteus* spp. in our study showed specific amino acids (isoleucine at the 1264 and 1281 positions, threonine at the 1282 position, alanine at the 1288 position [only in collared scops owl KU234], and methionine at the 1288 position).
difference in spotted wood owls, but we have no data on spotted wood owl RBCs to support this hypothesis. The high-resolution images obtained from computerized image analysis yielded better parameter values than those from conventional microscopy. Therefore, the morphometric values of Haemoproteus gametocytes might also be slightly different when obtained by different instruments or from different avian RBCs; regardless, morphological characteristics remain a gold standard for use in species identification of Haemoproteus [26]. We speculated that the identification of parasites via morphometry was difficult in Haemoproteus species. The greater number of Haemoproteus-positive owls detected by PCR methodology supported the suggestion of a higher sensitivity of molecular techniques compared with that from conventional microscopic examination in low parasitemia cases [28]. However, some same authors [27] and the other authors [18] have reported similar prevalences of hemoprotean parasites obtained from microscopy and PCR analysis. Nonetheless, blood smear examination is relatively inexpensive and provides valuable information. Thus, such examination is still suitable for field studies of parasites [5], comparative analysis [27], and molecular barcoding [29]. Demonstration of gametocytes in thin blood films remains a standard method for diagnosis [22] and species classification [3,26]. PCR-based information should be supported by observation of the blood stage of the parasite [28]. Because the majority of natural Haemoproteus infections are low and are difficult to identify at the species level using only morphological features, the development of new molecular markers is essential for future research [29].

H. syrnii showed the highest infection prevalence (22%) in tawny owl from Germany [17], although in our study H. noctuae was the most prevalent in both BO and CSO. These differences may be due to differences in the geographical distribution of hematozoans. The high prevalence of Haemoproteus-infection in BO and CSO in Thailand supports previous reports indicating that this parasite is the most common hemosporidian found in raptors throughout the world [17,22].

Although the ultrastructure of Haemoproteus gametocytes has been relatively well described [26], there are no reports of same for BO and CSO, especially for monocytes phagocytizing gametocytes. Numerous clearly defined micronemes similar to those documented by Valkiūnas [26] were not detected in the Haemoproteus from BO and CSO. The electron density and structure of the osmiophilic bodies were similar to micronemes [26], but we found fewer osmiophilic bodies; although they were easier to identify by using transmission electron microscopy.

Phylogeny branch evidence grouped the Haemoproteus sequences in our study into Parahaemoproteus. The nucleotide sequences were located in the Culicoidea spp. transmitted avian hemoproteozoan cluster [4]. Amino acid data were used to confirm the differences between our Haemoproteus isolates and H. noctuae (KP794612). All residues were located from the 1264 to 1288 positions of the cyt b protein, and our Haemoproteus sequences displayed unique residues.

**Table 5. Effect of Haemoproteus gametocytes on RBCs and nuclei in barn and collared scops owls**

| Parameter                     | Non-infected RBCs | Infected RBCs |
|-------------------------------|-------------------|---------------|
| Barn owls                     | (n = 56)          | (n = 36)*     | (n = 20)*     |

| Area of RBC (μm²)             | 72.1 ± 6.2a       | 77.5 ± 5.6b   | 70.4 ± 3.8a   |
| NDR                           | -                 | 0.8 ± 0.1     | 0.8 ± 0.1     |

Data are presented as mean ± SD. NDR = 2x/(x + y), where x and y were the width between the nucleus and cell membrane with and without the gametocyte. RBCs, red blood cells; NDR, nuclear displacement ratio. *H. noctuae, halteridial gametocytes. †H. noctuae, circumnuclear gametocytes. ‡H. syrnii. †Different letters in the same row indicate significantly differences between groups at p < 0.05.
The tree topology results showed unique clustering of *Haemoproteus* from 8 BOs and 4 CSOs. The *Haemoproteus* isolates exhibited both halteridial-shaped (KU86, 112, 163, 200, 202, 203, 248, 250, and 284) and circumnuclear-shaped (KU71, 120, and 132) mature gametocytes, which were similar to those of *H. noctuae* but displayed clear differences in molecular characteristics. Therefore, these *Haemoproteus* may comprise a new species or subspecies of *Haemoproteus* in strigid owls. Conversely, some species of *Haemoproteus*, such as *H. pallidus*, *H. minutes*, and *H. vacuolatus* exhibited different morphologies but showed cytb gene genetic divergence of less than 2% [16]. Based on molecular characteristics, *Haemoproteus* in KU127 CSO (KJ561457) was suggested to be *H. syrni*, although they differed in length and width from *H. syrni* in spotted wood owls [21]; although it should be *H. syrni* based on a morphological characteristic (lacking circumnuclear gametocytes) and phylogenetic analysis (closely related to *H. syrni*, KJ541480).

The results of the partial cytb gene analysis revealed that the *Haemoproteus* spp. of the 8 BOs and 7 CSOs analyzed in this study and the previously reported *H. noctuae* and *H. syrni* formed one large cluster (except KU234 and KU127). Therefore, the *Haemoproteus* spp. analyzed in this study were closely related to *H. noctuae* and *H. syrni*; moreover, *H. noctuae* was closely related to *H. syrni*. Although the *Haemoproteus* isolate from KU234 CSO was similar (96.5%) to *H. syrni* (EF607290), it was not included in a large cluster, suggesting that this strain was slightly distant from the other large cluster of our study and might be from a different lineage with 3.5% divergence. This result revealed that phylogenetic analysis using short sequences of partial cytb genes has limitations and might not be able to distinguish *H. noctuae* from *H. syrni* correctly. These data provide basic information that will be valuable in future studies of *Haemoproteus* in BO and CSO.

The results of this study highlight the hematology, morphometry, ultrastructure, and molecular characterization of *Haemoproteus* in BO and CSO from Thailand and also contribute to identifying the value of microscopy and molecular diagnosis in the study of avian blood parasites. The present study also provides morphological data on the molecular detection of 8 and 11 sequences of *Haemoproteus* from BO and CSO, respectively, which may be used as the basis for further study of *Haemoproteus* in these two owl species.
