(Dated: December 6, 2010)

In this letter we describe our novel photon regeneration experiment for the axionlike particle search using a x-ray beam with a photon energy of 50.2 keV and 90.7 keV, two superconducting magnets of 3 T, and a Ge detector with a high quantum efficiency. A counting rate of regenerated photons compatible with zero has been measured. The corresponding limits on the pseudoscalar axionlike particle-two photon coupling constant is obtained as a function of the particle mass. Our setup widens the energy window of purely terrestrial experiments devoted to the axionlike particle search by coupling to two photons. It also opens a new domain of experimental investigation of photon propagation in magnetic fields.

Photon propagation in magnetic fields is a long standing domain of research for QED tests and for particle searches beyond the standard model. All the experiments performed up to now have used a photon energy of the order of 1 eV (see [3] and Refs. therein). Higher photon energies have been proposed to increase the signal, in particular γ rays for QED test, or to increase the parameter space for particle searches, in particular x-rays [4].

As far as particle searches are concerned, photon regeneration experiments, also called “light shining through the wall” experiments, are an important tool in the search for massive particles that couple to photons in the presence of magnetic fields. Such particles are predicted by many extensions of the standard model. A very well known example is the standard axion, a pseudoscalar chargeless boson proposed to solve the strong CP problem i.e. the difference between the value of the neutron electric dipole moment predicted by QCD and its experimental value.

The principle of a photon regeneration experiment is to send a polarized photon beam through a region where a transverse magnetic field is present, and then to stop the photons by a wall. Since they hardly interact with matter, axionlike particles (ALPs) generated in the magnetic region upstream of the wall can pass through it. Behind the wall, a second magnetic field region allows to convert back ALPs into photons. Several photon regeneration experiments have been performed: none of them has ever detected regenerated photons. They have therefore set limits on the ALP-two photon coupling constant g and the particle mass m_a. The best limits can be found in Ref. [20].

Limits are usually given for masses m_a ≪ ω, where ω is the photon energy, but a detailed theoretical analysis of ALP-photon and photon-ALP conversion amplitudes valid for m_a ≲ ω can be found in Ref. [22]. Again, for all the photon regeneration experiments performed up to now, ω is of the order of 1 eV. Experiments searching for ALPs of astrophysical origin, such as ADMX [23] and CAST [24], provide better limits than the purely terrestrial ones. ADMX looks for galactic cold dark matter µev ALP conversion into microwave photons in a resonant cavity immersed in a static magnetic field, while CAST looks for axions or ALPs generated in the core of the sun. These ALPs travel to earth and are converted back into photons of a few keV in a static laboratory magnetic field. Due to the higher photon energy, the CAST limits extend up to masses on the order of a few eV [24]. These limits, however, depend on the model used to calculate the flux of ALPs to be detected. The critical sensitivity to these models is exposed by the recent proposal of an ALP with a 17 meV mass which could explain the observed spectral shape of the x-ray solar emission [25]. In this case ALPs coming from the sun’s interior would be reconverted into photons near the sun’s surface, thus escaping the detection by CAST.

Increasing the photon energy in photon regeneration experiments allows to test new regions of the m_a and g parameter space. The use of soft x-rays has been proposed in Ref. [5], namely at the VUV-FEL free electron laser at DESY, providing photons of energy between 10 eV and 200 eV. The use of hard x-rays from a synchrotron light source has been proposed in Ref. [6]. Synchrotron light sources provide photons with energy of several tens of keV, much higher than the photon energy available nowadays at free electron lasers.

In this letter we describe our photon regeneration experiment using x-ray beams with a photon energy of 50.2 keV and 90.7 keV, carried out at the European Synchrotron Radiation Facility (ESRF), France, on beamline ID06 [24]. Our setup consists of two superconducting magnets that provide magnetic fields of 3 T over a length of 150 and 97 mm respectively, and a Ge detector with a high quantum efficiency for the stated photon energies. This configuration widens the energy domain probed by...
purely terrestrial ALP searches. A counting rate of regenerated photons compatible with zero has been measured. We present the corresponding limits on the ALP-two photon coupling constant as a function of the particle mass. Thanks to the high photon energy, our limits extend to a parameter region where no model independent limits have been set so far. In particular our experimental results provide limits on the existence of 17 meV ALPs.

Our experimental setup is shown in Fig. 1. We use two different photon energies, $\omega = 50.2$ keV and 90.7 keV, corresponding to slightly different settings of the x-ray beamline. For 50.2 keV (resp. 90.7 keV), a Si(111) (resp. Si(311)) double crystal monochromator is adjusted to select x-rays emitted by the 5th (resp. 9th) harmonic of the cryogenic permanent magnet multipole undulator source U18, closed to a gap of 6.0 mm. The energy bandwidth is 7.3 eV (resp. 6.8 eV). For both energies, the size of the beam is $2 \times 2$ mm$^2$ and the synchrotron x-rays are horizontally polarized. The beam direction is stabilized by a feedback loop adjusting the pitch of the second monochromator crystal to ensure a position stability better than 0.1 mm at the entrance of the second magnet.

Most of the beam path is under vacuum in order to avoid air absorption. The incident flux is measured thanks to ionization chambers filled with 1 bar of nitrogen or krypton. Different ionization chambers placed along the beam path let us check for any photon loss due to beam misalignment for example. During data acquisition, the 30 cm long krypton filled ionization chamber, located just before the first magnet, is used to precisely monitor the incident flux. The beamline has delivered about $1.2 \times 10^{12}$ photons per second at 50.2 keV and $3.1 \times 10^{10}$ photons per second at 90.7 keV.

The magnetic fields are provided by two superconducting magnets with the field direction parallel to the x-ray polarization, the experiment being thus sensitive to pseudoscalar particles. Their diameter aperture is about 2 cm and the pressure inside the magnets is less than $10^{-4}$ mbar. Both magnets have been manufactured by Oxford Instruments. The first one has provided a maximum magnetic field $B_1 = 3$ T which can be regarded as uniform along the beam path over a length of $L_1 = 150$ mm. The second magnet was lent to us by the DUBBLE beamline (BM26) at the ESRF. It has also delivered $B_2 = 3$ T. The shape of its magnetic field along the beam direction can be approximated by a triangular shape with a half base length of $L_2 = 97$ mm, the maximum of 3 T being at the center of the magnet.

The magnets are located separately in the two lead shielded experimental hutches, EH1 and EH2 respectively, of the beamline. The safety shutter between EH1 and EH2 serves as the wall to block the x-ray beam. It consists of a 50 mm thick lead plate. Similarly, the x-ray regeneration and detection section is shielded by the radiation hutch EH2. The complete enclosure of the primary x-ray beam in EH1 and the additional shielding of EH2 lead to a comfortably low level of x-ray background radiation dominated by cosmic events.

The detection system is based on a 5 mm thick Ge detector (Canberra GL0055) cooled with liquid nitrogen. The sensitive area is 6 mm in diameter. X-ray photons arriving on the detector create electric charges proportional to the photon energy, which are amplified (Canberra 2024) and filtered by a single channel analyzer (Ortec 850) to reject events that do not correspond to the photon energy selected by the monochromator. This detection system combines an acceptable quantum efficiency of $\approx 99.98\%$ at 50.2 keV and $\approx 84\%$ at 90.7 keV, with a reasonably low dark count rate. This background count rate was measured at $(7.2 \pm 1.4) \times 10^{-3}$ photons per second while the x-ray beam was turned off, as shown on the first line of Table I. The error corresponds to 95% confidence level.

The following experimental protocol is used before each data acquisition. First, the monochromator is adjusted to select the desired energy while keeping an incident flux as high as possible. Then, the detector is moved about 20 cm sideways from the direct beam position. The safety shutter is opened, allowing the x-ray beam to propagate through both experimental hutches. In this position, the dominant radiation received at the detector are photons elastically scattered by air. This is used to adjust the upper and lower thresholds of the single channel analyzer such that only photons of the selected energy are counted. The upper (lower) threshold is 10% above (20% below) the voltage generated by the elastically scattered photons. Next, the detector is protected by Cu absorbers and it is moved back into the direct beam position to check its geometrical alignment. Finally, before data collection the safety shutter is closed and the Cu absorbers are removed. The procedure is repeated after data collection.
Results are summarized in Table I. The integration time $t_i$ is about 2 hours for each photon energy in two different configurations—with or without the magnetic fields. The count rate $N_c$ is the number of photons detected per second. The error on $N_c$ corresponds to 95% confidence level and is given by $2\sqrt{N_c/t_i}$ since the distribution of the detected photons is a Poisson distribution. The number of regenerated photons per second $N_p$ is the difference between count rates measured with and without the magnetic fields. We see that no excess count above the background level has been detected. Finally, the upper photoregeneration probability at 95% confidence level corresponds to the error on $N_p$ over the incident photon rate $N_{inc}$. It is $P = 2.2 \times 10^{-15}$ at 50.2 keV, and $P = 9.7 \times 10^{-14}$ at 90.7 keV.

The photon to ALP conversion and reconversion transition probability after propagating in vacuum over a distance $z$ in an inhomogeneous magnetic field $B$ may be written as:

$$p(z) = \left| \int_0^z dz' \Delta_\omega (z') \times \exp(i\Delta_\alpha z') \right|^2,$$

where $\Delta_\omega (z) = \frac{aB(z)}{2}$ and $\Delta_\alpha = \frac{m^2}{2\omega}$. Finally, the photoregeneration probability is:

$$P = \eta p_1 p_2,$$

with $\eta$ the detection efficiency, $p_1$ the conversion probability in the first magnet and $p_2$ the reconversion probability in the second magnet. These equations are correct for $m_a \ll \omega$.

Our experimental sensitivity limit for the ALP-two photon coupling constant versus mass is calculated by numerically solving Eqs. 1 and 2, using the upper photon regeneration probability experimentally measured. To this end, the real profiles of the magnetic fields along the beam direction provided by the manufacturers are used. Our limits at 95% confidence level are plotted in Fig. 2. In particular, $g < 1.3 \times 10^{-3}$ GeV$^{-1}$ for masses lower than 0.4 eV, and $g < 6.8 \times 10^{-3}$ GeV$^{-1}$ for masses lower than 1 eV. Our limits could be extended up to 90 keV [22], but because of the phase mismatching they decrease very rapidly when $m_a \gg \sqrt{\omega/L_{1,2}}$, thus becoming less interesting. Moreover, for such masses the probability oscillates so rapidly that its actual value depends critically on the exact value of the experimental parameters $L_{1,2}$ and $\omega$. In this case the level of confidence of corresponding limits is mostly limited by the confidence level on these experimental values. We believe that a detailed discussion of this issue is out of the scope of our letter.

We compare our limits to other limits obtained with laboratory experiments in Fig. 3. Our exclusion region is presented as the grey area. The best limits set by the search of extraterrestrial ALPs are the two hashed areas, namely the 95% confidence level exclusion region of CAST (diagonally hashed) [24], and the 90% confidence level exclusion region on microwave cavity experiments (horizontally hashed) [23, 33, 35]. Model predictions [36] are also shown as a dotted stripe (line in between: $E/N = 0.2$) [27, 28]. This figure shows that we have tested a new region of the $m_a$ and $g$ parameter space for purely terrestrial—model independent—experiments.

Our experiment could certainly be upgraded. A longer acquisition time would improve the limits, but an improvement of a factor of 2 requires a 16 times longer acquisition. This also applies for the photon flux and for

| X-ray beam | Magnets | $\omega$ (keV) | $t_i$ (s) | $N_{inc}$ (Hz) | $N_c$ (Hz) | $N_p$ (Hz) |
|------------|---------|---------------|-----------|---------------|-----------|-----------|
| OFF | OFF | 13913 | 0 | $(7.2 \pm 1.4) \times 10^{-3}$ | $(5.7 \pm 1.8) \times 10^{-3}$ | $(0.5 \pm 2.6) \times 10^{-3}$ |
| ON | OFF | 50.2 | 7575 | $1.2 \times 10^{12}$ | $(6.2 \pm 1.8) \times 10^{-3}$ | $(0.2 \pm 3.0) \times 10^{-3}$ |
| ON | ON | 50.2 | 7276 | $1.2 \times 10^{12}$ | $(7.9 \pm 2.0) \times 10^{-3}$ | |
| ON | OFF | 90.7 | 7444 | $3.2 \times 10^{10}$ | | |
| ON | ON | 90.7 | 7247 | $3.1 \times 10^{10}$ | $(8.1 \pm 2.2) \times 10^{-3}$ | |
FIG. 3: Limits on the ALP-two photon coupling constant $g$ as a function of the particle mass $m_a$ obtained by experimental searches. Our exclusion region is presented as the grey area. See text for more details.

detector noise rate. The latter could likely be improved by using the x-ray detector in anticoincidence with cosmic ray detectors put around it and/or in coincidence with the electron bunches circulating in the synchrotron ring. Using higher magnetic fields increases limits linearly, which is obviously more interesting. A static 15 T field can be reasonably envisaged. Longer magnets could provide higher limits but only at low masses since longer magnets reduce the coherence length of the photon-ALP oscillations and limits at higher masses. The best solution would be to increase the magnetic field $B$ and reduce the magnet length $L$ keeping the product $B \times L$ as high as possible.

Our experiment extends the search for photon oscillations into massive particles in the presence of magnetic fields to higher energies. The observed low background count rate clearly demonstrates the sensitivity of “shining through the wall” experiments with a synchrotron light source. Moreover we studied for the first time the propagation of x-ray photons in magnetic fields opening a new domain of experimental investigations.

This work has been performed in the framework of the BMV project. We acknowledge the ESRF for providing beam time on ID06 and financial support. The detection system has been kindly provided by the ESRF Detector Pool. We thank J.-P. Nicolin for his technical support. We thank W. Bras for kindly lending us one of the two superconducting magnets, P. van der Linden for its technical support and C. Cohen and M. Kocsis for their help with the Ge detector. Finally we thank A. Dupays and J. Jaeckel for fruitful discussions. We gratefully acknowledge the support of the Fondation pour la recherche IXCORE.
