ABSTRACT

Study of the primary anisotropies of the Cosmic Microwave Background (CMB) can be used to determine the cosmological parameters to a very high precision. The power spectrum of the secondary CMB anisotropies due to the thermal Sunyaev-Zel’dovich Effect (SZE) by clusters of galaxies, can then be studied, to constrain more cluster specific properties (like gas mass). We show the SZE power spectrum from clusters to be a sensitive probe of any possible evolution (or constancy) of the gas mass fraction. The position of the peak of the SZE power spectrum is a strong discriminatory signature of different gas mass fraction evolution models. For example, for a flat universe, there can be a difference in the $l$ values (of the peak) of as much as 3000 between a constant gas mass fraction model and an evolutionary one. Moreover, observational determination of power spectrum, from blank sky surveys, is devoid of any selection effects that can possibly affect targeted X-ray or radio studies of gas mass fractions in galaxy clusters.

Subject headings: Cosmology: observations, cosmic microwave background; clusters: intracluster medium, gas fraction

1. INTRODUCTION

Clusters of galaxies, being perhaps the largest gravitationally bound structures in the universe, are expected to contain a significant amount of baryons of the universe. Moreover, due to their large angular sizes, observational estimates of their total mass $M_T$ , the gas mass $M_g$ and hence the gas mass fraction ($f_g = \frac{M_g}{M_T}$) are easier. These estimates can be used as probes of large scale structure and underlying cosmological models. For example, the cluster $f_g$ would give a lower limit to the universal baryon fraction $\Omega_b/\Omega_m$. Determination of $f_g$ has been done by numerous people (White & Fabian, 1995; Mohr et al. 1999; Sadat & Blanchard, 2001) and the values are in agreement within the observational scatter. A point to be noted here is that the estimated $f_g$ depends on the distance to the cluster (i.e. $f_g \propto d_{ang}^{3/2}$). Hence, if $f_g$ is assumed to be constant, then in principle, one can use the ‘apparent’ evolution of $f_g$ over a large redshift range to constrain cosmological models (Sasaki 1996).

The question as to whether there is any evolution (or constancy) of gas mass fraction, however, is still debatable, with claims made either way. For example, Schindler (1999) has investigated a sample of distant clusters with redshifts between 0.3 to 1 and conclude that there is no evolution of the gas mass fraction. Similar conclusion has been drawn by Grego et al. (2000). On the contrary, Ettori and Fabian (1999) have looked at 36 high-luminosity clusters, and find evolution in their gas mass fraction (in both sCDM and ΛCDM universes). See also David et al., 1995; Tsuru et al. 1997; Allen & Fabian, 1998; Mohr et al. 1999). Observations suggest that, though $f_g$ of massive clusters ($\mathcal{T}_e > 5 KeV$) appears to be constant, low mass clusters with shallower potential wells may have lost gas due to preheating and/or post-collapse energy input (David et al. 1990, 1995; Ponman et al. 1996; Bialek et al. 2000). It is also well known that ICM is not entirely primordial and there is probably continuous infall of gas, thereby, increasing $f_g$ with time. Thus, there is considerable debate regarding the evolution of gas mass fraction.

The intracluster medium (ICM) has been probed mainly through X-ray observations, but also through the so called Sunyaev-Zeldovich effect (Zel’dovich & Sunyaev, 1969) in the last decade (see Birkinshaw 1999 for a review). The SZE effect from clusters is a spectral distortion of the CMB photons due to inverse Compton scattering by the hot ICM electrons, with its magnitude proportional to the Compton $y$-parameter, given by $y = \frac{k_B\sigma_T}{m_e c^2} \int n_e T_e dl$. Here, $k_B$ is the Boltzman constant, $\sigma_T$ is the Thomson scattering cross section, $m_e$ is the electron mass, and $n_e$ and $T_e$ are the ICM electron density and the temperature. Using bolometric SZE measurements, the $f_g$ has been obtained for a number of clusters (see Birkinshaw 1999). Recently, Grego et al. (2000) have made interferometric observations of SZE from a sample of 18 clusters. A major advantage of SZE over X-ray measurements is, SZE does not suffer from the $(1+z)^{-4}$ ‘cosmological dimming’, which makes SZE an useful probe of evolution of cluster gas mass fraction.

Other than the targeted SZE observations, non-targeted ‘blank sky’ surveys of SZE are one of the main aims of future satellite and ground based small angular scale observations (Holder & Carlstrom, 1999; or with AMiBa). Once the power spectrum is extracted from observations, comparison can be made with theory, to constrain cosmological parameters and relevant cluster scale physics. The SZE power spectrum as a cosmological probe has been well studied (Refregier et al., 1999; Komatsu & Kitayama, 1999), although its use as a probe of ICM has seldom been looked at.

Keeping such surveys in mind, in this Letter, we look at...
the SZE power spectrum as a probe of the ICM. We show it to be a very sensitive probe of the evolution (or constancy) of $f_g$. Measurements of the primary anisotropy would give us ‘precise’ values of cosmological parameters (like $h$, $\Omega_m$, $\Omega_A$, $\Omega_b$). Hence, for our calculations, we assume that we know the values of cosmological parameters and do not worry about their effect on the SZE power spectrum. Any feature of the SZE power spectrum is attributed to specific cluster physics (like gas content). We note that this method of probing $f_g$ is not biased from any selection effect that can occur while doing pointed SZE observations of X-ray selected clusters of galaxies, and hence is more desirable.

Current observations of primary CMB anisotropies suggest a flat universe with a cosmological constant (Padmanabhan and Sethi, 2000). For our calculations, we take a flat universe with $\Omega_m = 0.35$, $\Omega_b = 0.05$ and $h = 0.65$ as our fiducial model.

The paper is structured as follows. In the next section we discuss the distribution of clusters and model the cluster parameters. In §3, we compute the Poisson and clustering power spectrum from SZE and, finally, we discuss our results and conclude in §4.

2. THE SUNYAEV-ZEL’DOVICH EFFECT POWER SPECTRUM

2.1. Distributing the galaxy clusters

We set up an ensemble of galaxy clusters with masses between $10^{13} \leq M \leq 10^{16} M_\odot$, using the abundance of collapsed objects as predicted by a modified version of the Press-Schechter (PS) mass function (Press & Schechter 1974) given by Sheth and Tormen (1999). The lower mass cutoff signifies the mass for which one expects a well developed ICM. The gas mass is supposed to sit in the halo. The central gas density, $\rho_c$, is not biased from any cutoff signifies the mass for which one expects a well defined ICM. We probe up to redshifts of 5. Most of the power, however, comes from objects distributed at $z < 1$.

We use the transfer function of Bardeen et al. (1986), with the shape parameter given by Sugiyama (1995) and the Harrison - Zel’dovich primordial spectral index to calculate the matter power spectrum $P_m(k)$. The resulting COBE-FIRAS normalised (Bunn & White, 1997) mass variance ($\sigma_8$) is 0.9 for our fiducial model.

2.2. Modelling the cluster gas

We assume the ICM to follow a $\beta$-profile with $\beta = 2/3$ for simplicity. The other physical parameters of the clusters are determined using the virial theorem and spherical collapse model. We closely follow Colafrancesco & Vittorio (1994) in our modelling. We have for the gas density, $n_e(r) = n_e,0 \left(1 + \frac{r}{R_c}\right)^{-3\beta/2}$. We take the gas to be extended up to $R_c = pr_c$ with $p = 10$. The central gas density, $n_e,0$ is given by $n_e,0 = f_g \rho_0 (1 + X)^{-1} X$, where $X = 0.76$ is the average proton mass fraction and $\rho_0$ is the central gas mass density. To account for the fact that there is a final cutoff in the gas distribution we introduce a Gaussian filter at the cluster edge $R_c$ given by $n_e(r) \rightarrow n_e(r) e^{-r^2/\xi R_c^2}$, where $\xi = 4/\pi$ is the fudge factor.

We parametrize the gas mass fraction as

$$f_g = f_{g0}(1 + z)^{-s} \left( \frac{M}{10^{15} h^{-1} M_\odot} \right)^k,$$

where the normalization is taken to be $f_{g0} = 0.15$, is based on local rich clusters. We look at combinations of both mass and redshift dependence for a range of evolutionary models. In particular, we look at a case of strong evolution given by $k = 0.5$, $s = 1$ (Colafrancesco & Vittorio, 1994); $k = 0.1$, $s = 0.5$ (as suggested by Ettori and Fabian, 1999); $k = 0.1$, $s = 0.1$ (weak evolution); $k = 0$ (no mass dependence) and $s = 0$ (no redshift dependence).

For the core radius $r_c$ and the temperature, we use

$$r_c(\Omega_0, M, z) = \frac{1.69 h^{-1} Mpc}{p} \frac{1}{1 + z} \times \left[ \frac{M}{10^{15} h^{-1} M_\odot} \frac{178}{\Omega_0 \Delta_c} \right]^{1/3},$$

$$k_B T_c = 7.76 \beta^{-1} \left( \frac{M}{10^{15} h^{-1} M_\odot} \right)^{2/3} (1 + z) K eV.$$

Here, $\Delta_c(z)$ is the cluster overdensity relative to the background.

Putting everything in, we have the temperature distortion to be $\frac{\Delta T(\theta)}{T_{cmb}} = g(x) y(\theta)$, with

$$y(\theta) = \left( \frac{\sigma_n e^0 r_c k_B T_c}{m_e c^2} \right) \frac{\pi e^{1/\beta^2}}{\sqrt{1 + (\theta/\theta_c)^2}} \text{Erfc} \left( \frac{1 + (\theta/\theta_c)^2}{\xi p^2} \right).$$

The angular core radius $\theta_c = r_c/d_{ang}$. The spectral form of the thermal SZ effect is given by

$$g(x) = \frac{x^{4-2\beta}}{e^{x} - 1} \left[ x \coth(x/2) - 4 \right],$$

where $x = \hbar \nu / k_B T_{cmb}$. This specific spectral dependence of the thermal SZ effect can be used to separate it out from other CMB anisotropies (Cooray et al., 2000).

3. COMPUTING THE POWER SPECTRUM

The fluctuations of the CMB temperature produced by SZE can be quantified by their spherical harmonic coefficients $a_{lm}$, which can be defined as $\Delta T(\mathbf{n}) = T_{0}^{-1} \sum_{lm} a_{lm} Y_{lm}(\mathbf{n})$. The angular power spectrum of SZE is then given by $C_l = \langle |a_{lm}|^2 \rangle$, the brackets denoting an ensemble average. The power spectrum for the Poisson distribution of objects, can then be written as (Cole & Kaiser 1988, Peebles 1980)

$$C_l^{\text{Poisson}} = \int_0^{r_{max}} dz \frac{dV(z)}{dz} N_{min}^{M_{max}} dm \frac{dn(M, z_{in})}{dm} |y_l(M, z)|^2,$$

where $V(z)$ is the comoving volume and $dn/dm$ is the number density of objects.

Since these fluctuations occur at very small angular scales, we can use the small angle approximation of Legendre transformation and write $y_l$ as the angular Fourier
transform of $y(\theta)$ as $y_0 = 2 \pi \int y(\theta) J_0((l+1/2)) \theta \mathrm{d} \theta$ (Peebles 1980, Molnar & Birkinshaw 2000).

In addition to Poisson power spectra, one would expect contribution to a ‘correlation power spectrum’ from the clustering of the galaxy clusters. Following Komatsu and Kitayama (1999), we estimate the clustering angular power spectrum as

$$C_l^{\text{Clustering}} = \int_0^{l_{\text{max}}} \frac{dV(z)}{dz} P_m \times$$

$$\left[ \int_{M_{\text{min}}}^{M_{\text{max}}} \frac{dM}{dM} \frac{dn(M, z)}{dn} b(M, z) y(M, z) \right]^2,$$

where $b(M, z)$ is the time dependent linear bias factor. The matter power spectrum, $P_m(k, z)$, is related to the power spectrum of cluster correlation function $P_c(k, M_1, M_2, z)$ through the bias, i.e. $P_c(k, M_1, M_2, z) = b(M_1, z)b(M_2, z)D^2(z)P_m(k, z = 0)$ where we adopt $b(M, z)$ given by $b(M, z) = (1 + 0.5/\nu^4)^{0.06-0.02\nu}[(1 + \nu^2 - 1)/\delta_c]$ (Jing 1999 for details). This expression for the bias factor matches accurately the results of N-body simulations for a wide range in mass. In the above equation $D(z)$ is the linear growth factor of density fluctuation, $\delta_c = 1.68$ and $\nu = \delta_c/\sigma(M)$.

4. RESULTS AND DISCUSSIONS

We study the power spectrum of SZE from clusters of galaxies, under the assumption of a ‘precise’ and ‘a priori’ knowledge of the cosmological parameters. We also assume that in the $l$-range of relevance, thermal SZE from clusters of galaxies are the dominant contributors to the temperature anisotropy. The other secondary anisotropies are either smaller in strength or contribute at even higher $l$’s or have different spectral dependence (Aghanim et al., 2000; Majumdar et al., 2000).

We have plotted the Poisson SZE power spectrum in Fig1, left panel. Clearly, the primary feature distinguishing a non-evolutionary constant $f_g$ model from an evolutionary one is the position of the peak. The model with a constant $f_g$ peaks at a higher $l$-value and also has greater power. The constant $f_g$ model peaks at $l \sim 4000$. This result is in agreement with that of Komatsu & Kitayama (1999). If one assumes that there is no evolution of $f_g$ with redshift (i.e $s = 0$), the peak is at $l \sim 1100$, whereas in the case of no dependence on mass ($k = 0$), the peak is at $l \sim 2500$. Based on EMMSS data (David et al., 1999), Colafrancesco & Vittorio (1994) (and also Molnar & Birkinshaw 2000) model $f_g$ with $k = 0.5$ & $s = 1$. For this case, we see that the turnover is at a very low $l \sim 900$. Assuming a mild evolution ($k = 0.1, s = 0.1$), we get the peak at $l \sim 2100$. We also show results for ($k = 0.5, s = 0.5$) and ($k = 0.1, s = 0.5$). The last parametrization is based on the recent analysis of ROSAT data by Ettori & Fabian (1999).

It is evident that the difference, in the $l$-value of the peak of the constant $f_g$ scenario from an evolutionary one, can range between $l \sim 1500 - 3200$. The position of the peak thus is a strong discriminator signature of any evolution of $f_g$.

It is easy to understand the shift in the peak of the SZE power spectrum. Let us consider the case $s = 0$, i.e. $f_g$ depends only on total mass. From Eqn. (1), this means an enhanced reduction of $f_g$ of smaller mass clusters relative to the larger masses and so a reduction of power at larger $l$’s, (since smaller masses contribute at larger $l$). Hence, the peak shifts to a lower $l$. For the case $k = 0$, (i.e only redshift dependence), we now have structures at high $z$ contributing less to the power (than without a redshift dependence). Since from PS formalism, less massive structures are more abundant at high $z$, this negative dependence of $f_g$ on redshift cuts off their contribution more than the more massive clusters. Hence, once again there is less power at high $l$ and the peak shifts to lower $l$-value. The parametrization of Eqn. (1) affects the larger masses less, as evident from almost equal power seen at $l \leq 600$, for all models. The net effect is a reduction of power at smaller angular scales, and hence a shift in the position of the peak to a smaller multipole value.

We note that, these results are irrespective of the arguments given (see Rines et al., 1999) to explain any possible evolution of $f_g$. In their case, they assume $f_g$ to be constant and relies on the cosmology to change the angular diameter distance, so that there is an ‘apparent’ change in $f_g$. In such a case, if there is ‘actually’ even a slight evolution of $f_g$, then one can still account for it with a non-evolutionary model, by simply changing the cosmological parameters. Our method does not assume a priori any constancy (or evolution) of $f_g$ and tries to look for it.

In Fig1, right panel, we show the SZE clustering power spectrum. For all models, it falls of at a smaller $l$ w.r.t Poisson power spectrum. Since for clustering, the peak depends on the average inter-cluster separation, which is fixed once the cosmology is fixed, there is no appreciable spread of the peaks in $l$-space. The only difference is in their relative power w.r.t each other which depends on the total gas mass available to distort the CMB. Addition of the clustering power spectrum to the Poisson case results in slight shift of the peaks to lower $l$’s.

It maybe possible to measure the power spectrum of SZE with the ongoing and future high angular resolution CMB observations. In principle, observations with SUZIE, OVRO, BIMA and ATCA can probe the range in $l$ from $\approx 1000 - 7000$ and a frequency range of $\approx 2 - 350$ GHz. The SZE power spectrum would also be measured with increased precision by the proposed ALMA and AMiBA (which is geared for blank sky surveys).

Finally, let us comment on the validity and robustness of our results. In Fig2, we show results for an open universe ($\Omega_0 = 0.35, h = 0.65$). It is clearly seen that the difference in the peak position of constant $f_g$ and evolutionary models remain far apart (Infact, for same parameters of $k = 0.5, s = 1$, the difference increases to $\approx 4500$ from that of $\approx 3000$ in a flat universe). It is seen that the turnover of the SZE power spectrum is insensitive to the mass cutoff, since main contribution to the anisotropy comes from clusters with $10^{14}M_\odot < M < 10^{15}M_\odot$. In Fig2, we also indicate the effect of having a more compact gas distribution with $p = 7$. We see that shift in the peaks are negligible (though the height is reduced a little) and an uncertainty as to how far the gas extends is not major. The use of a single $\beta$ to model the full gas distribution introduces little error, though a $\beta$-model fits the inner cluster regions better. This is because the major contribution to the anisotropy comes from around the core region, and increasing $\beta$ slightly decreases the overall distortion, without touching the peak. Also, a modified $M - T$ relation (more
suitable for ΛCDM) does not change the conclusions of this paper (although amplitude of distortion slightly changes). For a more detailed analysis, however, one should take better observationally supported gas density and temperature profiles (see Yoshikawa & Suto, 1999). These points will be discussed in greater detail in a future publication.

In conclusion, we have computed the angular power spectrum of SZE from clusters of galaxies. We have shown the position of the peak of the power spectrum to bear a strong discriminatory signature of different $f_g$ models. One of the goals of arc minute scale observations of the CMB anisotropy is to measure the SZE power spectrum from blank sky surveys. Such observational results can be used to constrain $f_g$ models. This also has the added advantage of being devoid of uncertainties that can creep through ‘selection biases’ in estimating the $f_g$ using pointed studies of X-ray selected galaxy cluster. Our method, thus, provides a powerful probe of evolution (or constancy) of gas mass fraction and can potentially resolve the decade long debate.

The author wishes to thank Joe Mohr and Biman Nath for critical comments, Sunita Nair and Dipankar Bhattacharya for valuable suggestions and Pijush Bhattacharjee for encouragements. He also wishes to thank the Ramon Research Institute, Bangalore. After the completion of this work, we learnt about a complimentary work by Carlstrom & Holder (2001) which looks at changes in gas profiles due to preheating and its effect on SZE.

Fig. 1.— The Poisson (left panel) and clustering (right panel) power spectra due to SZE from galaxy clusters for different $f_g$ models. For both the panels, the thick solid line corresponds to constant $f_g$ model, the thick dashed line has no evolution with redshift and the thick dash-dotted line has no evolution with total mass. The thin lines are for the cases: a) $k=0.5$, $s=1$; b) $k=0.5$, $s=0.5$; c) $k=0.1$, $s=0.5$ and d) $k=0.1$, $s=0.1$. 
Fig. 2.— The Poisson SZE power spectra are plotted for different cosmologies and with different extension of the gas mass. The solid lines are for a $\Lambda$CDM, with $\Omega_m = 0.35, \Omega_\Lambda = 0.65, h = 0.65$, and the thin lines are for OCDM with $\Omega_m = 0.35, h = 0.65$. The OCDM lines have been multiplied by a factor of 10 in the plot. The solid and dashed lines are for gas mass extending up to $10r_c$, whereas the dash-dotted and the dotted lines are for extension up to $7r_c$.
