Abstract. We present a simple microscopic realization of a pseudo-Nambu-Goldstone (pNGB) boson Higgs scenario arising from the breaking of $SO(5) \rightarrow SO(4)$. The Higgs constituents are explicitly identified as well as the interactions responsible for forming the bound state and breaking the electroweak symmetry. This outcome follows from the presence of four-fermion interactions with a super-critical coupling, and uses the Nambu-Jona-Lasinio mechanism to break the global $SO(5)$ symmetry. The Higgs potential is found to be insensitive to high energy scales due to the existence of an approximate infrared fixed point. The appearance of vector resonances is described and the correspondence with other proposals in the literature established. The model described here is significantly simpler than other recent ultraviolet completions of pNGB scenarios. The observed Higgs mass can be accommodated, and agreement with electroweak precision tests achieved in certain regions of parameter space. There are also new vector-like fermions, some of which may lie within reach of the LHC. In addition, we predict a heavy standard model singlet scalar in the multi-TeV range. The amount of fine-tuning required in the model is studied. Finally, we show that such a scheme can be completed in the ultraviolet by a renormalizable theory.
1 Introduction

Theories with fundamental scalars usually suffer from a quadratic sensitivity to the ultraviolet (UV) that leads to naturalness problems when hierarchically separated energy scales are present. Historically this has motivated extensions of the Standard Model with either new symmetries that protect the theory against short distance details (e.g. supersymmetric models) or with an UV completion where the scalar particle is not fundamental (e.g. technicolor (TC) models).
The usual TC models were constructed in analogy with QCD and the Higgs was identified with the elusive $\sigma$-meson. This interpretation is now excluded since the Higgs was found to be light and narrow [1, 2]. However, it was also proposed in the 1980’s that the Higgs boson could be a pseudo-Nambu-Goldstone (pNGB) composite state from the spontaneous breaking of a global symmetry [3–6] (for a nice review, see [7]). The study of effective theories of this sort eventually led to what is generically known as composite Higgs (CH) models. CH models experienced a revival about a decade ago with their incorporation into extra-dimensional theories in AdS spaces [8, 9].

Several CH models have been proposed recently and it is timely to explore what are the requirements on the underlying theory that gives rise to these effective theories at low energies, generating the correct electroweak symmetry breaking (EWSB) scale and the Higgs mass. Here we start exploring this question by describing a concrete non-supersymmetric UV completion with the required low-energy properties (see also [10, 11]). A number of supersymmetric UV completions of CH scenarios have also been proposed [12–14].

Implicit in much of the literature is the idea that the underlying physics involves strong dynamics, which eventually triggers symmetry breaking and the formation of bound states. One can then try to model these strong interactions as effective 4-fermion interactions and study them in the context of the Nambu-Jona-Lasinio (NJL) framework. In the incarnation studied in this paper one has three energy scales: a scale $\Lambda$ associated with the mass of heavy degrees of freedom that, when integrated out, generate the 4-fermion interactions with strength $G = \mathcal{O}(1/\Lambda^2)$ — we will sometimes refer to it as the compositeness scale; a scale $f$ associated with the breaking of a global symmetry through the vacuum expectation value (vev) of an effective scalar field that generates Goldstone bosons; and finally $v$, the scale of electroweak (EW) breaking that is generated through a 1-loop effective potential from (small) effects that violate the global symmetry explicitly.

We are largely inspired by the seminal paper by Bardeen, Hill and Lindner [15] (see also the early works [16–18]) who studied a model where the Higgs boson is a composite state of top quarks, arising from 4-fermion top-quark interactions à la NJL [19, 20]. There, a self-consistent solution of the gap equation with a nonzero $\langle \bar{t}t \rangle$ condensate for a strong enough coupling breaks a global symmetry $SU(2)_L \times SU(2)_R \rightarrow SU(2)_V$ generating the Goldstone bosons that are absorbed by the EW gauge bosons in the usual symmetry breaking mechanism, which in this case has an explicit custodial symmetry. The solution to the gap equation determines the mass of the top quark and predicts a new composite scalar particle, associated with the bound state of $\bar{t}t$ that is identified with the Higgs boson.

In the approximation where gauge loops are neglected, the Higgs mass is predicted to be $m_h \approx 1.32 m_t$ [15]. Moreover, at the scale $\Lambda$ the scalar kinetic term approaches zero (the “compositeness condition”), and hence the top Yukawa coupling reaches a Landau pole. It turns out that this is only possible for a rather heavy top quark. In spite of its attractiveness as a model of dynamical symmetry breaking without fundamental scalars, the most minimal model fails since it gives both a too heavy top quarks and a too heavy Higgs boson.

Prior to the Higgs discovery, the problem with the top quark mass was solved in models
that include the top quark see-saw (TSS) mechanism \cite{21, 22}. However, after the 2012 discovery we know that the Higgs boson is lighter than the top quark. As a result, the problem of too heavy a Higgs in NJL-type models (with a TSS) has been brought up again recently. In particular, the idea to enlarge the pattern of global symmetry breaking in order to realize the Higgs boson as a pNGB has been put forward in \cite{23–28}.

In this paper we consider a UV complete scenario that realizes the Higgs as a pNGB of the symmetry breaking $SO(5) \rightarrow SO(4)$. As is well-known \cite{9}, this leads to a minimal set of NGB’s while containing a custodial symmetry \cite{29} and allowing for the “custodial protection” of the $Z b_L \bar{b}_L$ vertex \cite{30}. We point out that four-fermion interactions, which may easily arise from a renormalizable model, can naturally realize the above symmetry breaking pattern. This leads to simpler realizations than have been explored in the literature, and goes beyond the CCWZ \cite{31, 32} non-linear realizations of the symmetry employed in most of the composite Higgs literature. We also show that the heavy spin-1 sector, which would be responsible for cancelling the quadratic divergences in the Higgs mass parameter due to the SM gauge bosons, arises quite naturally in this framework. In regards to fermions, we focus on the top sector and proceed guided by the principle of minimality. We find that the most minimal model is typically ruled out by electroweak precision tests (EWPT) due to a negative 1-loop contribution to the Peskin-Takeuchi $T$-parameter \cite{33}. However, a slightly extended version allows agreement with precision measurements. We find that it is necessary to include a moderate amount of (soft) custodial breaking in the BSM sector which, however, does not spoil the calculability implied by the custodial $SO(4)$. We also compute the dynamically generated Higgs potential, and explore the region of parameter space where the observed Higgs mass can be reproduced. It is interesting that the presence of IR quasi-fixed points make the low-energy predictions largely insensitive to the uncertainties associated with the underlying strong dynamics.

This paper is organized as follows. In Section 2, we review the NJL symmetry breaking mechanism as applied to the present $SO(5)$ scenario. We remind the reader of the IR quasi-fixed point that relates the fermion and (radial) scalar masses. We also present the minimal fermionic sector that leads to a realistic low-energy field content, as well as other natural extensions inspired by an analogy with models of partial compositeness (on which we also comment). Spin-1 resonances are then introduced and shown to be naturally associated with a “hidden local symmetry”.

Sections 3 and 4 are devoted to the dynamical breaking of the EW symmetry. This arises from the explicit breaking of the $SO(5)$ symmetry by the gauge interactions, as well as by certain mass terms in the fermionic sector. Of particular note is that the $SO(5)$ breaking is not only soft (so that the quadratic sensitivity to the UV of the weak scale is absent), but that there is a second IR quasi-fixed point that largely shields the low-energy predictions from the UV details. We also study the interplay between EWSB and EWPT. In Section 5 we analyze the resulting tuning in our scenario, which itself depends on a relatively small number of parameters. Interestingly, we find that although the new resonances are typically in the TeV range, the theory could be technically natural due to a nearby enhanced symmetry
point. Finally, in Section 6, we present a simple renormalizable model that can serve as a UV completion to our present work, generating the necessary four-fermion operators with the required $SO(5)$ symmetry. Section 7 contains our summary and conclusions.

We also include a number of appendices. In App. A we present details of the Fierz rearrangements necessary to relate the renormalizable theory of Section 6 and the $SO(N)$ NJL model. We summarize our $SO(5)$ conventions in App. B, while in App. C we provide a few technical details of the evaluation of the Higgs potential due to the spin-0, spin-1/2 and spin-1 resonances. Finally, App. D discusses a technical point related to the IR divergences that appear when expanding the potential in powers of the Higgs vev, and App. E summarizes the RG equations that are used to establish the presence of the IR quasi-fixed points mentioned above.

2 Description of the Model

2.1 NJL Breaking of $SO(5)_L \times U(1)_X \rightarrow SO(4)_L \times U(1)_X$

The breaking of the global group $G = SO(5)_L \times U(1)_X$ can be achieved by strongly coupled four-fermion operators along the lines of [19, 20]. The minimal fermionic field content to achieve this breaking is comprised of a left handed $5_2^{\frac13}$, denoted by $F_L$, and a right-handed $1_0^{\frac23}$, denoted by $S_R$.\footnote{The normalization of the $U(1)_X$ generators is chosen for later convenience, when we discuss the embedding of the SM electroweak symmetry $SU(2)_L \times U(1)_Y \subset SO(5)_L \times U(1)_X$, and provide further details of the fermionic sector necessary to reproduce the observed low-energy physics. In addition, we allow each of the fermion fields to carry a color index, so that the symmetry of the theory will always contain an additional $SU(N_c)$ factor. This factor is understood to be weakly gauged and, with $N_c = 3$, will be identified with the QCD interactions. We will assume that all fields are in the fundamental or singlet representations of $SU(N_c)$, depending on whether they are associated with the quarks or leptons of the SM. Except when there could be some ambiguity in how the color indices are contracted, we will not display them explicitly.}\ The kinetic terms read thus

$$L_F = \sum_{j=1}^5 i\bar{F}_L^j \gamma^\mu F_L^j + i\bar{S}_R \gamma^\mu S_R.$$ \hfill (2.1)

This Lagrangian is actually accidentally invariant under the larger group $G_0 \equiv SU(5)_L \times U(1)_L \times U(1)_R$, with $SO(5)_L \subset SU(5)_L$ and $U(1)_X = [U(1)_L \times U(1)_R]_{\text{diagonal}}$, under which $F_L$ transforms as a $5_2^{\frac13,0}$ and $S_R$ as a $1_0^{\frac23}$. However, while the fermionic fields decompose under $G_0 \rightarrow G$ simply as

$$5_2^{\frac13,0} \rightarrow 5_2^{\frac13}, \quad 1_0^{\frac23} \rightarrow 1_0^{\frac23},$$ \hfill (2.2)

the decomposition of the composite scalar field $\bar{S}_R F_L$ is reducible

$$5_2^{\frac13,0} \rightarrow 5_0 + 5_0,$$ \hfill (2.3)
where the real and imaginary parts of $\bar{S}_R F_L$ form two different irreducible representations of $G$. As a consequence it is possible to write down two four-fermion operators that are separately invariant under $G$. They read

$$L_S = \frac{G_S}{2} \left( \sum_{a=1}^{N_c} \bar{S}_{R,a} F_{L,a}^\dagger S^a_R \right)^2, \quad L'_S = -\frac{G'_S}{2} \left( \sum_{a=1}^{N_c} \bar{S}_{R,a} F_{L,a}^\dagger - \bar{F}_{L,a} S^a_R \right)^2,$$

(2.4)

where, to avoid ambiguity, we also show the color index contractions (see Footnote 1), labeled by the index $a$. Such contractions will be implicitly understood from here on. For $G_S = G'_S$ the Lagrangian $L_S + L'_S = 2G_S |\bar{S}_R F_L^i|^2$ becomes indeed invariant under the extended group $G_0$, and hence $G_S \neq G'_S$ parametrizes the explicit breaking $G_0 \to G$.

Whenever the four-fermion couplings $G_S$ or $G'_S$ are greater than some critical value [20], the composites $\bar{S}_R F_L^i$ become dynamical scalar fields that condense and break the global symmetry. For both $G_S \approx G'_S$ super-critical, this would lead to additional light scalar composites (in particular, a second Higgs doublet under $SU(2)_L$). Here we effectively restrict ourselves to the minimal Lagrangian $L_S$ by imposing that only the coupling $G_S$ be super-critical, while $G'_S$ is assumed to be sub-critical and does not give rise to any light composites. In other words, the four-fermion interactions of $L_S$ lead to a spontaneous symmetry breakdown (reviewed below) that produces light (p)NGB states, while the interactions in $L'_S$ do not induce any such breaking. If $G'_S$ is not close to criticality, the additional loosely bound fermion bilinears will have masses close to the cutoff, and it may not even be appropriate to think of them as well-defined scalar resonances in their own right. Thus, the assumption that $G_S$ is slightly larger than $G'_S$, and close to criticality, allows us to focus from the start on a minimal set of light degrees of freedom that are relevant to the low-energy physics. We will present in Section 6 a simple UV model that realizes this picture. Alternatively, one could allow for the additional bound states from $L'_S$ (or even from further four-fermion operators) and then add appropriate symmetry breaking terms to the low-energy theory to make them sufficiently heavy. The latter is essentially the approach taken in Refs. [23, 27]. Note that in this second approach, in general, one would need to take into account such intermediate thresholds to establish a connection between the low-energy theory and the theory at the UV scale $\Lambda$, where the physics is most appropriately described by the four-fermion interactions discussed above. By assuming that $G'_S$ is sub-critical, so that there are no such additional scalar states below $\Lambda$, a more straightforward connection between the UV and IR can in principle be established.

We now rewrite the four-fermion Lagrangian in terms of real scalar auxiliary fields $\Phi^i$ in the $5_0$ representation of $G$ as

$$L_S = -\frac{1}{2G_S} \phi^2 - \Phi (\bar{S}_R F_L + \text{h.c.}) ,$$

(2.5)

which can be seen to be equivalent to the form given earlier after integrating out the auxiliary scalar fields. The Lagrangian $L_F + L_S$ generates, through fermion loops, a kinetic term for
Φ, thus making this field dynamical at scales sufficiently below the matching scale \( \Lambda = G_s^{-1/2} \) (at which Eq. (2.5) holds). They also generate tachyonic corrections to the tree level Φ mass, eventually leading to the spontaneous breaking of \( SO(5)_L \) to its subgroup \( SO(4)_L \), which we identify with the \( SU(2)_L \times SU(2)_R \) symmetry group of the SM (in the limit that the hypercharge and Yukawa couplings are turned off). The Goldstone bosons of this breaking transform in a 4 of \( SO(4)_L \) and hence can be identified with the SM Higgs field. We will trade the scalar mass parameter for the physical symmetry breaking scale \( \hat{f}^2 = \langle \Phi \rangle^2 \). Finally, fermion loops also generate a quartic self coupling, so that at low energies \( \mathcal{L}_S \) reads
\[
\hat{\mathcal{L}}_S = \frac{1}{2} (\partial_\mu \Phi)^2 - \frac{1}{4} \lambda \left( \Phi^2 - \hat{f}^2 \right)^2 - \xi \Phi (\bar{S}_R F_L + \text{h.c.}) ,
\]
where the Yukawa coupling \( \xi \) appears after canonical normalization (we do not change the name for \( \Phi \) for notational simplicity). The fact that the kinetic term for \( \Phi \) vanishes at \( \Lambda \) is equivalent to saying that \( \xi \) reaches a Landau pole at that scale, a condition also known as the compositeness boundary condition.

In the NJL model, the quartic self coupling \( \lambda \) is a prediction due to an IR quasi-fixed point for the quantity \( \lambda/\xi^2 \) [15]. Indeed, in the \( SO(N) \) NJL model, we find
\[
16\pi^2 \beta_{\xi^2} = (4N_c + N + 5)\xi^4 ,
\]
\[
16\pi^2 \beta_\lambda = 2(N + 8)\lambda^2 - 8N\xi^4 + 8N\xi^2\lambda ,
\]
which possess an IR stable fixed point at
\[
\lambda = a_*\xi^2 ,
\]
where (for \( N_c = 3 \) and \( N = 5 \) \( a_* = \frac{12}{13} \approx 0.92 \)). While this type of fixed point is present in any scalar-fermion system (even in the SM [34]), the compositeness condition – i.e. the fact that \( \xi \) is strong in the UV – guarantees that this fixed point is reached rapidly in the IR. A mild correction to this fixed point behavior is induced by nonzero gauge couplings. We illustrate the effect of QCD corrections in Fig. 1 (see App. E for the RG equations that include the QCD effects). Remarkably, the theory remains completely predictive even in the presence of gauge corrections, in the sense that the IR value for \( \lambda \) is still fully determined from the IR value of \( \xi \) (see the solid blue line in the figure). Notice that the QCD corrections are numerically small, for instance \( a_*(\xi = 2) \approx 0.86 \), compared to the fixed-point value of Eqs. (2.7), \( a_* \approx 0.92 \).

The \( SO(5) \) basis employed so far simplifies the description of the global symmetry breaking, but the SM quantum numbers of the fields are not manifest. For the remainder of this paper we thus switch to a different basis defined as
\[
(Q^1_L, Q^2_L) \equiv \frac{1}{\sqrt{2}} \left( \begin{array}{c} F^1_L + iF^3_L \\ -F^2_L + iF^1_L \end{array} \right), \quad S_L \equiv F^5_L .
\]

\[\text{There is also a UV fixed point at } a_* = -1. \text{ In order to reach the IR fixed point one must have } \lambda/\xi^2 > -1 \text{ at the scale } \Lambda.\]
Figure 1. RG flow of the couplings $\lambda$ and $\xi$. The dashed line is the exact IR fixed point $a_*=12/13$ that is reached in the absence of gauge interactions. QCD corrections introduce a mild dependence $a_*(\xi)$ represented by the solid blue line. The thin red lines are examples of trajectories, with the distance between the dots corresponding to one e-fold of running. For simplicity, we neglect the running of the strong coupling constant.

where $Q^1_L$ and $Q^2_L$ transform under $SU(2)_L \times U(1)_Y \subset SO(5)_L \times U(1)_X$ as $2_{-\frac{7}{5}}$ and $2_{\frac{7}{5}}$ respectively, and $S_L$ (as well as $S_R$) as $1_{\frac{2}{3}}$.

Thus, the first doublet $Q^1_L$ has the same quantum numbers of the left-handed top-bottom doublet, while the second doublet $Q^2_L$ has the exotic hypercharge $\frac{7}{6}$. The vector-like singlet $(S_L, S_R)$ has the same quantum numbers as the right handed top. In order to obtain a chiral spectrum which at low energies contains just a left handed $2_{\frac{2}{3}}$ (to be identified with the SM $(t_L, b_L)$ doublet) and a right-handed $1_{\frac{2}{3}}$ (to be identified as the SM $t_R$) we will have to introduce more states in incomplete $G$ multiplets. We will describe the top sector in detail in Section 2.2, and continue focusing in this section on the minimal content required to achieve the dynamical breaking above. In the new basis, the scalar sector becomes

$$\left(\tilde{\phi}, \phi\right) \equiv \frac{1}{\sqrt{2}} \left(\Phi^4 + i\Phi_3, \Phi^2 + i\Phi^1\right), \quad \phi^5 \equiv \Phi^5$$

where $\phi$ transforms in $2_{\frac{2}{3}}$ and $\tilde{\phi}$ as $2_{-\frac{7}{5}}$ of $SU(2)_L \times U(1)_Y$. The reality property $\Phi^* = \Phi$ translates into the well-known relation $\phi^* = -i\sigma_2\tilde{\phi}$. In this basis, the Yukawa Lagrangian

\[3\text{See App. B, where we summarize the conventions for the two different } SO(5) \text{ bases, as well as the embedding of } SU(2)_L \times U(1)_Y \subset SO(5)_L \times U(1)_X.\]
in Eq. (2.5) reads
\[ \mathcal{L}_S = -\frac{1}{G_S} \phi^\dagger \phi - \frac{1}{2G_S} \phi_5^2 - (\bar{Q}_L S R \tilde{\phi} + \bar{Q}_L^2 S R \phi + h.c.) - \bar{S} S \phi_5 , \] (2.11)
while at sufficiently low-energies, where a sizable kinetic term for \( \Phi \) has been radiatively generated, together with quartic scalar self-interactions, the Lagrangian in Eq. (2.6) reads
\[ \mathcal{L}_S = (\partial_\mu \phi)^2 + \frac{1}{2} (\partial_\mu \phi_5)^2 - \frac{1}{4} \lambda \left( 2\phi^2 + \phi_5^2 - \hat{f}^2 \right)^2 - \xi \left[ (\bar{Q}_L S R \tilde{\phi} + \bar{Q}_L^2 S R \phi + h.c.) - \bar{S} S \phi_5 \right] . \] (2.12)
When \( \langle \phi_5 \rangle = \hat{f} \) (and \( \langle \phi \rangle = 0 \) ), the breaking \( SO(5)_L \rightarrow SO(4)_L \) ensues, generating four NGB’s that transform as a doublet of \( SU(2)_L \) and can thus be identified with the SM Higgs field. These \( G/H \) Goldstone bosons are parameterized by introducing a unitary matrix \( U \) as
\[ \hat{\Phi} = \mathcal{H} U e_5 , \] (2.13)
where \( \hat{\Phi} = (\tilde{\phi}, \phi, \phi_5)^T \) and \( e_5 \) is the unit vector pointing along the \( \phi_5 \) direction.

We have introduced here the real scalar SM singlet \( \mathcal{H} \) that we will refer to as the radial mode in the following, and that acquires the vacuum expectation value \( \langle \mathcal{H} \rangle = \hat{f} \). At the IR quasi-fixed point one has
\[ m_\mathcal{H}^2 = 2\lambda \hat{f}^2 = 2a\xi^2 \hat{f}^2 , \] (2.14)
and the mass of the radial mode becomes a prediction of the model once the dynamical fermion mass \( m_f = \xi \hat{f} \) is fixed. The situation is of course completely analogous to the relation between the Higgs and top masses in the seminal paper [15], where the Higgs boson was identified with the radial mode.

Radiative effects arising from small explicit \( SO(5)_L \) symmetry breaking terms can lead to a vacuum that is slightly misaligned with the vacuum above, in which case the EW symmetry will be spontaneously broken. Such a misalignment can be parametrized by an angle \( s_v \ll 1 \) between \( \langle \hat{\Phi} \rangle \) and \( \hat{f} e_5 = (0, 0, 0, 0, \hat{f}) \), so that there is a separation of scales between the EW scale and \( \hat{f} \) (further details will be discussed later). In this case
\[ \langle \tilde{\phi} \rangle = \frac{1}{\sqrt{2}} \begin{pmatrix} s_v \\ 0 \end{pmatrix} \hat{f} , \quad \langle \phi \rangle = \frac{1}{\sqrt{2}} \begin{pmatrix} 0 \\ s_v \end{pmatrix} \hat{f} , \quad \langle \phi_5 \rangle = c_v \hat{f} . \] (2.15)

The particle content introduced so far allows for precisely one fermion mass term that is invariant under the SM gauge symmetries,
\[ \mathcal{L}_F^{mass,0} = -\mu_{SS} \bar{S} S . \] (2.16)
It preserves only the subgroup \( SO(4)_L \) and hence violates explicitly the global \( SO(5)_L \) symmetry. It is the analogue of current quark masses in models of chiral symmetry breaking.
Such a term is in fact easily seen to be equivalent to a tadpole term for the scalar field $\phi_5$, via the field redefinition $\phi_5 \rightarrow \phi_5 - \mu_{SS}$ in Eq. (2.11) together with (2.16), which eliminates the mass term and instead generates the tadpole term (see also Ref. [23])

$$\mathcal{L}_T = \frac{\mu_{SS}}{G_S} \phi_5.$$  \hspace{1cm} (2.17) 

We define $\tau \equiv \xi \mu_{SS}/G_S$, which is the relevant tadpole term after canonical normalization as in Eq. (2.6). We will see that although EWSB can be achieved without such a term, the measured value for the Higgs mass can typically only be reproduced for $\mu_{SS} \neq 0$. We note that for fixed symmetry breaking scale $\hat{f}$, the mass of the radial mode changes to

$$m_{H}^2 = 2a_s \xi^2 \hat{f}^2 + \frac{\tau}{\hat{f}}.$$

(2.18)

We will see later that this correction is rather small, and the mass is well approximated by the leading term, Eq. (2.14).

### 2.2 The Top Sector and Partial Compositeness

We now complete the model to include a realistic top sector by means of the TSS mechanism [21]. This bears some resemblance to the partially composite top models typically introduced in the recent CH literature [35–38, 40–44]; a more complete set of references to the rather extensive literature can be found in the recent review [45]. We will explicitly make the connection between the two approaches, but one should keep in mind that in our case all fermions are elementary, and the distinction between “composite” and “elementary” is purely formal.

The fermionic sector of the model so far contains a chiral doublet with the quantum numbers of the left-handed top-bottom, an exotic (chiral) left-handed doublet of hypercharge $7_6$, and a vector-like right handed top. It is manifestly symmetric under the global group $G$ [and in particular contains an unbroken custodial $SO(4)_L$], but does not reduce to the SM top sector at low energies. The minimal solution is to introduce the right handed fields $Q^2_R$ and $t_R$ with EW quantum numbers $2_7^g$ and $1_2^w$ respectively, and write the soft $G$-breaking mass mixing terms:

$$\mathcal{L}^{mass,1}_F = -\mu_{QQ} Q^2_L Q^2 - \mu_{tS} S_L t_R + h.c.$$  \hspace{1cm} (2.19) 

In particular, no new dimensionless $G$-breaking couplings are introduced.\textsuperscript{4} One notices that our model thus naturally realizes the TSS mechanism, in which the top Yukawa coupling arises only after integrating out the heavy vector-like top $S$ [21].

To leading order in $s^2_\psi$ – the misalignment angle that parameterizes EWSB – the approximate mass eigenvalues in the fermionic sector of this “minimal” model are given by

$$m_{S}^2 = \xi^2 \hat{f}^2 + \mu_{tS}, \hspace{1cm} m_{Q}^2 = \mu_{QQ}, \hspace{1cm} m_{t}^2 = \frac{s^2_\psi \xi^2 \hat{f}^2 \mu_{tS}^2}{2 m_{S}^2}.$$  \hspace{1cm} (2.20) 

\textsuperscript{4}Unlike the mass terms in Eq. (2.16) the operators in Eq. (2.19) are not equivalent to tadpole terms, as $t_R$ and $Q^2_R$ are not part of the condensate.
Subleading corrections will in particular split the charge $\frac{2}{3}$ from the charge $\frac{5}{3}$ states in $Q^2$. These eigenvalues are not changed by the tadpole term, which only redefines $\hat{f}$.

A (formally) very similar concept to the TSS mechanism is partial compositeness (PC) of the top quark (see [46] for an early model and [47] for a modern view). One distinguishes a $G$-symmetric (or at least $H$-symmetric) sector, made up of “composite” fermions, coupled via mass mixing terms to a set of “elementary” fermions that do not come in complete $G$ multiplets. The latter, in particular, do not possess direct Yukawa couplings to the composite Higgs. In this last sense, one could formally refer to the fields $Q^1_L$, $Q^2_L$, $S_L$ and $S_R$ in our setup as “composite”, and the fields $Q^2_R$, $t_R$ as “elementary”. However, the connection to other CH constructions based on partial compositeness still would seem to be imperfect, since in such CH models the elementary sector typically consists of just the SM fermions, and (consequently) the composite sector is entirely vectorlike. The connection of our setup to other CH models recently considered in the literature can be made more direct by adding the $2^1_6$ states $q_L$ and $Q^1_R$. With such a field content one could label $t_R$ and $q_L$ as “elementary”, with all other states labeled as “composite”. The field content just described is summarized in Table 1. The composite sector allows now for a global symmetry $SO(4)_L \times SO(4)_R$, where $(Q^1_L, Q^2_L)$ transform as $(4, 1)$, $(Q^1_R, Q^2_R)$ transform as $(1, 4)$ and all other fields transform as singlets. This symmetry is broken softly by mass terms such as Eq. (2.19) or mass terms of the form:

$$L^{mass,2}_F = -\mu_{QQ} Q^1_L Q^1_R - \mu_{qQ} \bar{q}_L Q^1_R .$$

For $\mu_{QQ} = \mu'_{QQ}$, the composite sector has an exact custodial $H \equiv SO(4) = [SO(4)_L \times SO(4)_R]_{\text{diagonal}}$ global symmetry, that is only broken by mixing with the elementary fields $q_L$ and $t_R$. Taking $\mu_{QQ} \neq \mu'_{QQ}$ then corresponds to (soft) custodial breaking in the composite sector, which as we will see can be of phenomenological importance. Note that Eqs. (2.16), (2.19) and (2.21) are the most general mass terms consistent with $SU(2)_L \times U(1)_Y$, given the field content of Table 1.
The approximate spectrum of the “extended” model is then given by Eqs. (2.20) but with the top mass modified to
\[ m_t^2 = \frac{s^2 \xi^2 \mu_s^2 \mu_Q^2}{2 m_S m_Q^2}, \] (2.22)
due to the additional masses in Eq. (2.21), together with an additional state with approximate mass
\[ m_Q^2 = \mu_{QQ}^2 + \mu_{qQ}^2. \] (2.23)

The minimal model discussed at the beginning of this section can be recovered in the limit \( \mu_{qQ} \to \infty \), and in PC language it features a “mostly composite LH top”. Note that one can make the connection to other CH models even sharper by adding a vector-like \( SU(2)_L \) singlet \((S'_L, S'_R)\) so that \( \Psi_L = (Q^1_L, Q^2_L, S_L) \) and \( \Psi_R = (Q^1_R, Q^2_R, S'_R) \) transform as a vectorlike \( 5 \) of \( SO(5) \), with \((S_R, S'_L)\) a vector-like \( SO(5) \) singlet: in this scenario the “composite sector” is explicitly \( SO(5) \) [and not only \( SO(4) \)] invariant, the symmetry being reduced from \( SU(5) \) down to \( SO(5) \) due to the 4-fermion interactions discussed in the previous section. Writing a mass term for \((S'_L, S'_R)\) breaks this \( SO(5) \) symmetry softly and allows to decouple these additional states. We therefore see that the minimal or extended models can be obtained from a softly broken \( SO(5) \) invariant composite sector in an appropriate limit, which still leaves the \( SO(5)_L \) symmetry discussed in Subsection 2.1 untouched.

We will examine the “minimal” model with just the states \((Q^1_L, Q^2_L, S_L), S_R, Q^2_R \) and \( t_R \), with the symmetry breaking Lagrangian (2.19), as well as the “extended” model with the additional \( Q^1_R, q_L \) and the symmetry breaking Lagrangian Eq. (2.21). While it is possible to achieve realistic electroweak breaking within the minimal model, we always find a negative contribution to the \( T \) parameter which makes compatibility with EWPT challenging. The extended model on the other hand does not suffer from this problem. We will not analyze the “fully \( SO(5) \) invariant model” that includes also the states \((S'_L, S'_R)\) discussed above, since it does not introduce a qualitatively new feature compared to the extended model (which itself allows to introduce a controlled amount of custodial breaking that is not present in the minimal model). Before analyzing these points in more detail, we will discuss the spin-1 sector of the NJL scenario.

2.3 The Spin-1 Sector

In this section we turn to the composite vector resonances that are predicted within our model. The latter appear very naturally as gauge-bosons of a hidden local symmetry [48]. Modeling the spin-1 resonances allows us to understand how the loop contributions to the (dynamically generated) Higgs potential are cut off by these heavy states.

One first notices that the NGB’s defined by Eq. (2.13) can be eliminated from the Yukawa couplings in Eq. (2.12) by a fermionic field redefinition of the form
\[ \left( \begin{array}{c} Q_L \\ S_L \end{array} \right) = U_L \left( \begin{array}{c} Q_L \\ S_L \end{array} \right), \quad S_R = U_R S_R, \] (2.24)
with \( U e_5 = U_L e_5 U_R^\dagger \), and \( Q_L = (Q_L^1, Q_L^2)^T \), \( Q_L = (Q_L^1, Q_L^2)^T \). One obvious possibility is the choice

\[
U_L = U , \quad U_R = 1 .
\]  

(2.25)

However, this choice is ambiguous up to a local \( H_{\text{HLS}} \equiv SO(4) \times U(1)_X \) transformation that acts on \( U_L \) and \( U_R \) from the right. This ambiguity defines a so-called Hidden Local Symmetry (HLS) \cite{48} and Eq. (2.25) corresponds to the unitary gauge. Notice that outside the unitary gauge, the matrix \( U_L \) and the phase \( U_R \) also contain the NGB’s of the HLS. It is furthermore convenient to parameterize \( U_R \) and \( U_L \) by \( U_1 \) and \( U_5 \) defined as \(^6\)

\[
U_R \equiv (U_1)^{\frac{2}{3}} , \quad U_L \equiv U_5 (U_1)^\frac{2}{3} .
\]  

(2.26)

The field \( U_1 \) transforms under \( U(1)_X \) with unit charge and the field \( U_5 \) is an element of \( SO(5) \) only.

We will refer to the basis defined in Eq. (2.24) as the HLS basis and denote its fields with calligraphic letters. Note that these fields transform as singlets of the global group \( G \) but transform non-trivially under \( H_{\text{HLS}} \).\(^7\) The only fields that transform under \( G \) are the NGB’s in \( U_5 \) and \( U_1 \). After the above transformation, one obtains

\[
\mathcal{L}_F = i(\bar{Q}_L, \bar{S}_L) \gamma^\mu \left( \partial_\mu + U_3^1 \partial_\mu U_5 + q_X U_1^1 \partial_\mu U_1 \right) \left( \begin{array}{c} Q_L \\ S_L \end{array} \right) + i\bar{S}_R \gamma^\mu \left( \partial_\mu + q_X U_1^1 \partial_\mu U_1 \right) S_R ,
\]  

(2.27)

where \( q_X = \frac{2}{3} \), and

\[
\mathcal{L}_S = - \frac{1}{2G_S} \mathcal{H}^2 - \mathcal{H} \mathcal{S} \mathcal{S} .
\]  

(2.28)

The Cartan connections appearing in \( \mathcal{L}_F \) ensure that the Lagrangian is fully invariant under the gauge symmetry \( H_{\text{HLS}} \). We will see now that they will become dynamical composite gauge fields, in full analogy to the scalar composites above.

In addition to the scalar four-fermion channels, we add the corresponding vector channels

\[
\mathcal{L}_V = - \frac{G_\rho}{2} (J^A)^2 - \frac{G_X}{2} (J^X)^2 ,
\]  

(2.29)

with the conserved \( SO(5)_L \) and \( U(1)_X \) currents \(^8\)

\[
J^{A \mu} = (\bar{Q}_L, \bar{S}_L) T^A \gamma^\mu \left( \begin{array}{c} Q_L \\ S_L \end{array} \right) , \quad J^{X \mu} = q_X (\bar{Q}_L \gamma^\mu Q_L + \bar{S}_L \gamma^\mu S_L + \bar{S}_R \gamma^\mu S_R) .
\]  

(2.30)

\(^5\)In addition, the fields \( U_{L,R} \) transform under the full global group \( G \) acting from the left.

\(^6\)Notice that the \( U(1)_X \) parts of \( U_L \) and \( U_R \) must coincide, as they transform identically under the Abelian part of \( H_{\text{HLS}} \), i.e. formally we have \( [U_L^1 \partial_\mu U_L]^X = U_R^1 \partial_\mu U_R = \frac{2}{3} U_1^1 \partial_\mu U_1 \).

\(^7\)The construction of this section could be generalized to the “full \( SO(5) \) symmetric” model discussed at the end of Section 2.2, from which the minimal and extended models can be obtained after decoupling certain states. For instance, using the notation of Eq. (2.24), one could rotate \( (Q_R, S_R^T) = U_L (Q_R, S_R^T)^T \), while leaving the “elementary” \( q_L \) and \( t_R \) unchanged. For simplicity, we do not keep track of these fields in this section.

\(^8\)The normalization of the generators is \( \text{tr} T^A T^B = \delta^{AB} \).
In full analogy to the scalar Lagrangian $L_S$, we now introduce spin-1 auxiliary fields

$$L_V = \frac{1}{2G_\rho} (A_\mu^\rho)^2 + \frac{1}{2G_X} (A_\mu^X)^2 + A_\mu^A J^{A\mu} + A_\mu^X J^{X\mu}. \quad (2.31)$$

In the HLS basis, Eq. (2.24), it is then natural to define new vector fields

$$A_\mu^A = [U_5^\dagger (A_\mu + i \partial_\mu) U_5]^A,$$

$$A_\mu^X = A_\mu^X + i U_1^\dagger \partial_\mu U_1. \quad (2.32)$$

Indeed, one checks that the definitions Eq. (2.32) are precisely the connections coupling to the fermions, and hence define their covariant derivatives in the HLS basis [see Eqs. (2.27), (2.31)]:

$$D_\mu = \partial_\mu - i T^A A_\mu^A - i q_X A_\mu^X. \quad (2.33)$$

Denoting the $SO(4)_L$-generators by $T^a$ and the $SO(5)_L/SO(4)_L$ generators by $T^\tilde{a}$ (see App. B), observe that only $(A_\mu^a, A_\mu^X)$ transform as gauge fields of $H_{HLS}$ while $A_\mu^{\tilde{a}}$ transform homogeneously.

At the UV matching scale, $\Lambda$, one ends up with the Lagrangian

$$L_F + L_S + L_V = i (\bar{Q}_L, \bar{S}_L) \frac{}{} \hat{D} \left( \begin{array}{c} Q_L \\ S_L \end{array} \right) + i \bar{S}_R \hat{D} S_R - \frac{1}{2G_S} \mathcal{H}^2 - \mathcal{H} \bar{S} S + \frac{1}{2G_\rho} \left( A_\mu^A - i U_5^\dagger \partial_\mu U_5 \right)^2 + \frac{1}{2G_X} \left( A_\mu^X - i U_1^\dagger \partial_\mu U_1 \right)^2. \quad (2.34)$$

The gauging of the EW subgroup of $G$ proceeds by the substitution $\partial_\mu U_{1,5} \rightarrow D_{\mu}^{SM} U_{1,5}$ (no other fields transforms under $G$), with

$$D_{\mu}^{SM} U_5 = [\partial_\mu - iw_i \partial_\mu T_i^L - ib_\mu T_R^3] U_5,$$

$$D_{\mu}^{SM} U_1 = (\partial_\mu - ib_\mu) U_1, \quad (2.35)$$

where $T^L_i$ ($i = 1, 2, 3$) are the $SU(2)_L$ generators and $T_R^3$ is the third isospin generator of $SU(2)_R$ [see Eq. (B.3)]. One also introduces the kinetic terms

$$L_G = - \frac{1}{4g_0^2} (w_{\mu\nu})^2 - \frac{1}{4g_0^2} (b_{\mu\nu})^2. \quad (2.36)$$

RG running induces kinetic terms for $A_\mu$ and $\mathcal{H}$,

$$L_K = - \frac{1}{4g_\rho^2} (\mathcal{F}^{\rho}_{\mu\nu})^2 - \frac{1}{4g_X^2} (\mathcal{F}^{X}_{\mu\nu})^2 - \frac{1}{2} (\nabla_\mu \mathcal{H})^2, \quad (2.37)$$

with

$$\nabla_\mu \mathcal{H} = (\partial_\mu - i A_\mu^{\tilde{a}} T^\tilde{a}) e_5 \mathcal{H}, \quad (2.38)$$
and where we normalized canonically the field $\mathcal{H}$ in full analogy to Eqs. (2.6) or (2.12), but kept a convenient non-canonical normalization for the spin-1 fields.

Putting all the ingredients together, the Lagrangian of the model reads

$$
\mathcal{L} = i(\bar{Q}_L, \bar{S}_L)\mathcal{D}(Q^L_S) + i\bar{S}_R\mathcal{D}S_R + \frac{1}{2}(\nabla_\mu \mathcal{H})^2 - \frac{1}{4}\lambda (\mathcal{H}^2 - f^2)^2 - \xi \mathcal{H}\bar{S}S
$$

$$
+ \frac{1}{4}f_\rho^2 \left( A^A_{\mu} - [U^4_3 D^{SM}_{\mu} U_5] A \right)^2 + \frac{1}{4}f_X^2 \left( A^X_{\mu} - [U^4_1 D^{SM}_{\mu} U_1] \right)^2
$$

$$
- \frac{1}{4g_\rho^2} (F_\mu^\nu)^2 - \frac{1}{4g_X^2} (F_X^\mu)^2 - \frac{1}{4g_0^2} (w_{\mu\nu})^2 - \frac{1}{4g_0^2} (b_{\mu\nu})^2 ,
$$

(2.39)

together with Eqs. (2.33), (2.35) and (2.38).\(^9\) For later convenience, we introduced the decay constants $f_\rho^2 = 2G_\rho^{-1}$ and $f_X^2 = 2G_X^{-1}$ of the $SO(5)_L$ and $U(1)_X$ resonances, respectively. The physical NGB decay constant $f$ is then obtained after integrating out the coset resonances and is given by

$$
f^{-2} = \hat{f}^{-2} + f_\rho^{-2} .
$$

(2.40)

The physical spin-1 masses (before EWSB) are given by

$$
m_{\rho}^2 = \frac{g_\rho f_\rho^2}{2} , \quad m_a^2 = r_v^{-1} m_{A}^2 , \quad m_X^2 = \frac{g_X f_X^2}{2} ,
$$

where $r_v \equiv \frac{f^2}{f_\rho^2} < 1 ,

(2.41)

where the index $\rho$ denotes the $SO(4)_L$ resonances and the index $a$ the $SO(5)_L/SO(4)_L$ ones. The remaining spin-1 states are massless in this approximation and can be identified with the SM gauge bosons. The corresponding gauge couplings are given in terms of the fundamental parameters by $1/g^2 = 1/g_0^2 + 1/g_\rho^2$ and $1/g_X^2 = 1/g_0^2 + 1/g_\rho^2 + 1/g_X^2$.

In a large part of the literature on NJL models, the couplings $g_\rho$ and $\xi$ are studied in the so-called fermion loop approximation, in which only the planar fermion loops – leading in the number of fermion colors $N_c$ – are kept [49]. In this case, the beta functions are one-loop only, and in particular are positive, hence rapidly decreasing the couplings $\xi, g_\rho$ in the IR. This allows one to conclude that the compositeness boundary condition $\xi, g_\rho = 4\pi$ at a UV scale $\Lambda$ can indeed be consistent with relatively weakly coupled states $g_\rho, \xi \ll 4\pi$ with masses below the compositeness scale $\Lambda$. The real-world value of the number of colors being $N_c = 3$, the validity of this approximation is far from obvious.

As it turns out, there is a fundamental difference in the RG running of the nonabelian coupling $g_\rho$ and the Yukawa coupling $\xi$ once the diagrams subleading in $N_c$ are included (such as loops of the actual composite states $\mathcal{H}$ and $A_V$). While the full 1-loop contribution to $\beta_\xi$ remains positive, the one for $\beta_{g_\rho}$ switches sign due to the negative contribution of

---

\(^9\)It only remains to add terms associated with the fermionic extension as well as the soft-breaking terms in Eqs. (2.19) or (2.21), as discussed in Section 2.2 and Footnotes 7 and 8.
the gauge self interactions, \( g_\rho \), at least for \( N_c = 3 \) and large enough global groups such as \( SO(5) \). Since beyond the large \( N_c \) approximation we would in principle need to take into account higher loop contributions (at least near \( \Lambda \) where \( \xi, g_\rho \sim 4\pi \)), one cannot reach any safe conclusion as to whether any composite states \( A_V^\mu \) below \( \Lambda \) are present or not.

To shed more light on this issue, it is useful to imagine there was such a relatively weakly coupled state \( g_\rho \ll 4\pi \) with mass \( m_V \ll \Lambda \). Then the \( \beta \) function can safely be approximated by its one-loop value, and evolving the coupling \( g_\rho \) towards the UV will further decrease it. One would tend to conclude that a compositeness boundary condition \( g_\rho = 4\pi \) can never be reached. However, the Yukawa couplings will start increasing and will eventually impact the running of \( g_\rho \) via higher-loop effects. Similarly, the NGB that make up the longitudinal components of the spin-one resonances are expected to become strongly coupled in the UV, triggering a breakdown of perturbative unitarity. Although this is expected to happen only near the compositeness scale (that we might define as \( \xi(\Lambda) = 4\pi \) in this case) it cannot be said with certainty if these effects are able to sufficiently increase \( g_\rho \) to allow for a compositeness boundary condition at such scales.

In conclusion, the IR value for \( g_\rho \) – unlike the coupling \( \xi \) – cannot be predicted. We will leave it as a completely free parameter of the model, keeping in mind the possibility that the composite states \( A_V^\mu \) could be strongly coupled with a mass near the cutoff.\(^{10}\) We will see that unless \( g_\rho \) is very close to \( 4\pi \), our predictions depend very little on its precise value. In practice we can simply ignore the RG running of all couplings in the UV and trade the value of the UV scale \( \Lambda \) for the IR value of \( \xi \). The scalar self coupling \( \lambda \) remains predicted due to the IR quasi-fixed point.

Before closing this section, we comment on two further aspects directly connected to the spin-1 sector.

**Connection to 2-site models**

Interestingly, our Lagrangian Eq. (2.39) is equivalent to a two-site model. Recall that a two-site model is defined as follows. The first site has global group \( G_0 = SO(5) \) of which only the SM subgroup is gauged.\(^{11}\) On the second site one introduces a CCWZ [31, 32] type breaking of the group \( G_1 = SO(5) \) to \( H_1 = SO(4) \), parameterized by a field \( \Phi \). The two sites interact via link fields, \( \Omega \), which transform in the bi-fundamental of \( G_0 \times G_1 \). Focusing on the spin-1 part, the Lagrangian is thus given by [50, 51]

\[
\mathcal{L} = -\frac{1}{4g_0^2} \text{tr}(F_{\mu\nu}^0)^2 - \frac{1}{4g_1^2} \text{tr}(F_{\mu\nu}^1)^2 + \frac{f_1^2}{2} \text{tr} D_\mu \Omega^\dagger D_\mu \Omega + \frac{1}{2} |D_\mu \Phi|^2 .
\]  

(2.42)

The covariant derivatives are

\[
D_\mu \Omega = \partial_\mu \Omega - iA_\mu^0 \Omega + i\Omega A_\mu^1 ,
\]  

(2.43)

\[
D_\mu \Phi = \partial_\mu \Phi - iA_\mu^1 \Phi ,
\]  

(2.44)

\(^{10}\)It is worth noticing that the running of the Abelian coupling \( g_X \) does not suffer from this issue, and can be computed reliably.

\(^{11}\)For simplicity, we omit in this discussion the \( U(1)_X \) factors.
where $A_0$ are the “elementary” gauge fields and $A_1$ the composite ones. In the last term of Eq. (2.42), $\Phi = \hat{f}Ue_5$ accomplishes the breaking $G_1 \to H_1$. The matrix $\tilde{U}$ contains the Goldstone bosons of this breaking on the second site, while the link field $\Omega$ contains the NGB of the breaking to $G = (G_0 \times G_1)_{\text{diagonal}}$. Going to the gauge $\tilde{U} = 1$ we precisely recover our Lagrangian with the identifications

$$\Omega = U_5, \quad f_1 = f_\rho, \quad g_1 = g_\rho.$$  \hfill (2.45)

Finally, we point out that the Lagrangian of Eq. (2.42) (and hence the spin-1 sector of our model) is actually equivalent to the most general, left-right symmetric Lagrangian of one complete set of $G$ resonances, if and only if the spin-1 sum rules in Eqs. (3.13) and (3.14) of [52] hold.

**Tree-level $S$-parameter from the vector resonances**

One of the most sensitive constraints on any composite Higgs model comes from the electroweak $S$ parameter, and its largest contribution is provided by the spin-1 resonances. Since our spin-1 sector is quite general and basically the same as in any composite Higgs model, it is worthwhile to consider at this stage the constraints implied by $S$. It can be computed as (see App. C)

$$S = -16\pi \Pi_{3B}'(0) = 4\pi s_v^2 f^2 \left( \frac{1}{m_\rho^2} + \frac{1}{m_a^2} \right) = 8\pi s_v^2 \frac{1 - r_v^2}{g_\rho^2}$$  \hfill (2.46)

Using the most recent oblique fit (with $U = 0$) [53]

$$S = 0.06 \pm 0.09, \quad T = 0.1 \pm 0.07$$  \hfill (2.47)

with a correlation of $\rho = 0.91$, one can place bounds on the parameters. At $T = 0$ the 95% C.L. interval for $S$ is $[-0.13, 0.017]$, while the SM point $S = T = 0$ roughly sits on the 90% C.L. contour. For $r_v = 0.5$ we find that $g_\rho = 3$ (6) requires $f \gtrsim 2.7$ (1.3) TeV. These bounds can be alleviated (made worse) if quantum corrections yield negative (positive) contributions to $S$ or positive (negative) contributions to $T$.

**2.4 Parameter Space of the Model**

The parameter space of the model is spanned by the couplings $\xi$, $g_\rho$, the symmetry breaking VEV $\hat{f}$, the NGB decay constant $f$ and the fermionic mass parameters $\mu_{QQ}$, $\mu_{Q}^\prime$, $\mu_S$ and $\mu_Q$.\footnote{We will analyze first the case where the tadpole term $\tau$ vanishes, and only include this parameter at a second stage in our analysis. Also, as we show in App. C.1, when $g_X^2 \gg g_0^2$ the $U(1)_X$ spin-1 resonance induces only minor effects.} There are eight parameters that can be expressed in terms of the masses $m_S$, $m_Q$, $m_Q^\prime$, $m_\rho$, $m_a$, and $m_t$ and two mixing angles:

$$s_R \equiv \frac{\mu_S}{m_S}, \quad s_L \equiv \frac{\mu_Q}{m_Q}, \quad s_{L,R} = \sin \alpha_{L,R}. \hfill (2.48)$$
The mass of the radial mode can be expressed in terms of these parameters as

$$m_H = \sqrt{2a_* c_R} m_S .$$  \hfill (2.49)

Since we have two conditions from electroweak breaking, we can eliminate the angles $s_L, s_R$, and the radial mass will be a prediction in terms of the other masses alone. Moreover, the electroweak splitting for the doublet will also be predicted.

Note that the mass condition for the top quark in Eq. (2.22) in this parametrization reads

$$m_t = \frac{m_S}{\sqrt{2}} s_v s_L s_R c_R ,$$  \hfill (2.50)

which in particular implies the inequality

$$m_S \geq 2 y_t f ,$$  \hfill (2.51)

where we used that the gauge boson masses determine $s_v = v_{SM}/f$ with $v_{SM} = 246$ GeV.

We will often use the notation

$$r_v \equiv \frac{m_t^2}{m_a^2} , \quad r_f \equiv \frac{m_Q^2}{m_S^2} , \quad r'_f \equiv \frac{m'_Q^2}{m_S^2} ,$$  \hfill (2.52)

to denote ratios of the various masses.

### 3 Remarks about the pNGB Effective Potential

One of the interesting features of the previous construction is that the Higgs boson appears quite explicitly as a bound state of fermions, and that its potential is generated dynamically. Since the Higgs is a pNGB of the breaking $SO(5) \to SO(4)$, the generated potential must be proportional to the couplings that break $SO(5)$ explicitly. In the spin-1 sector, the breaking arises from the gauging of the SM subgroup (hence the effects are proportional to $g$ and $g'$). In the fermionic sector, the parameters that break the $SO(5)$ symmetry are $\mu_{tS}$, $\mu_{QQ}$ and $\mu'_{QQ}$.\footnote{In the extended model, there can also exist contributions proportional to $\mu_{qQ}$. These are finite.} Note that the explicit breaking in the fermionic sector is soft. As we will see, at 1-loop order, the dominant effects are proportional to a certain combination of the previous parameters, such that when $\mu_{tS} = \mu_{QQ} = \mu'_{QQ}$ and the $SO(5)$ symmetry is restored, the corresponding contributions vanish. One attractive feature of many recent pNGB Higgs constructions is that the explicit breaking of the underlying symmetry whose spontaneous breaking leads to the pNGB’s is “super-soft”, i.e. it causes the Higgs potential to depend little or not at all on the details of the UV completion, resulting in a completely predictive model of EWSB.\footnote{In N-site models, the potential is finite up to a fixed order in the loop expansion. Often, sensitivity to the UV physics at the scale $\Lambda$ can be introduced at sufficiently high order. In extra-dimensional construction the Higgs potential is finite due to locality in the extra-dimension.} We will see that this holds true in our case, due to an interesting twist that is due to the RG running above the symmetry breaking scale.
Due to the shift-symmetry, the effective potential depends on the angular variable $s_h = \sin(h/f)$. We give general formulas and analytic approximations for our setup in App. C. In this section we simply highlight the main ingredients. If one formally expands the potential in powers of $s_h$, one has the parameterization

$$V = -\frac{\alpha}{2}s_h^2 + \frac{\beta}{4}s_h^4 + \mathcal{O}(s_h^6),$$

(3.1)

where, as mentioned above, the explicit breaking of the global $SO(5)$ symmetry generates nonzero values for $\alpha$ and $\beta$. As discussed in App. D, the naive expansion of the potential in powers of $s_h$ introduces a logarithmic IR divergence in $\beta$. A more careful analysis shows that this divergence is roughly cut by the $W$ or top masses, but the details of how this happens are not very important for the following discussion.

We start with the contributions to $\alpha$ and $\beta$ from fermion loops. As it turns out, the top sector introduced in Section 2.2 is not enough to render the top-loop contribution to the NGB potential completely finite. However, the UV sensitivity is softened and only a logarithmic divergence of the Higgs mass remains. This fact can easily be understood as follows. Let us parameterize a $\text{SO}(5)_L$ violating mass splitting in the Higgs potential as

$$L_{\text{mass}} = -\frac{1}{2}m_4^2|\phi_5|^2 - m_1^2|\phi|^2 = -\frac{1}{2}m_1^2(|\phi_5|^2 + 2|\phi|^2) - \delta m^2 |\phi|^2$$

(3.2)

The renormalization of the universal $\text{SO}(5)_L$ symmetric mass operator $\phi_5^2 + 2|\phi|^2 = \mathcal{H}^2$ is quadratically divergent, but contains no NGB’s. To renormalize the $\text{SO}(5)_L$ violating (NGB-dependent) mass operator $2|\phi|^2 = \mathcal{H}^2 s_h^2$, one needs two fermionic, $\text{SO}(5)_L$ violating mass insertions as shown in Fig. 2, thus reducing the divergence to a logarithmic one. By an analogous argument one can easily see that the one-loop renormalization of operators quartic in $\phi$ and $\phi_5$ other than the $\text{SO}(5)_L$ symmetric one are completely finite. The logarithmic divergence for $\delta m^2$ is proportional to the combination of mass insertions

$$\mu^2_{\text{eff}} \equiv 2\mu_{IS}^2 - \mu_{QQ}^2 - \mu_{QQ}^2,$$

(3.3)

where the various masses were defined in Eqs. (2.19) and (2.21). A vanishing of this quantity would indicate a softer (actually finite) UV behavior, similar to the general sum-rules found in Ref. [52]. However, we will not assume $\mu_{\text{eff}} = 0$ in this paper. As a consequence, we are forced to introduce a counterterm for the mass splitting $\delta m^2$. Once such a counterterm is introduced, it also receives multiplicative (logarithmically divergent) renormalization from scalar loops.

A major point that we would like to stress is that, remarkably, the introduction of a counterterm for the mass squared of the Goldstone boson does not reduce the predictivity of our model. The reason is similar to the prediction of the quartic self-coupling in terms of the Yukawa coupling that we encountered in Section 2.1. In fact, in the absence of gauge interactions, the RG-equations for $\mu_{\text{eff}}$ and the NGB mass $\delta m^2$ are

$$\beta_{\mu_{\text{eff}}} = \frac{\xi^2}{16\pi^2}\mu_{\text{eff}}^2, \quad \beta_{\delta m^2} = \frac{3\xi^2}{4\pi^2}\mu_{\text{eff}}^2 + \frac{\lambda + 3\xi^2}{4\pi^2}\delta m^2.$$  

(3.4)
The coupling $\mu_{\text{eff}}$ only runs due to the anomalous dimension of the left handed fields, Eq. (E.1), while $\delta m^2$ contains the above mentioned logarithmically divergent fermion and scalar contributions. The crucial observation is that the system in Eq. (3.4) has a fixed point at

$$\delta m^2 = - r_* \mu_{\text{eff}}^2 ,$$

with $r_* \equiv \frac{156}{191} \approx 0.81$. This fixed point is IR stable and hence any unknown UV value for $\delta m^2$ is eliminated along the RG flow. As was the case with the ratio $\lambda/\xi^2$, QCD corrections induce a mild dependence of $r_*$ on $\xi$. \(^{15}\) This effect is illustrated in Fig. 3, and results in slightly smaller values of $r_*$, e.g. $r_*|_{\xi=2} \approx 0.72$. One also observes that the asymptotic line is reached more slowly than in the case of the quartic coupling.

The RG flow discussed so far applies to the regime above the masses of the fermionic and scalar resonances. The full effective potential is computed in App. C which is used for our numerical analysis in Section 4. We can cross-check our claims above with this explicit calculation by combining the scalar and fermion loop contributions, and substituting the fixed-point conditions Eqs. (2.8) and (3.5), obtaining

$$\alpha_0 + \alpha_{1/2} = r_* \mu_{\text{eff}}^2 \frac{f^2}{M} \left(1 + \frac{11}{16\pi^2} \xi^2 \log \frac{M}{m_{\tilde{H}}} \right) + \text{finite} ,$$

where $M$ is the renormalization scale. For the purpose of this discussion, we have chosen the IR cutoff as $m_{\tilde{H}}$, the mass of the radial scalar mode [see Eq. (2.14)], assuming that the remaining resonances are somewhat lighter and therefore contribute to the running with full strength above $m_{\tilde{H}}$.\(^{16}\) The first term thus corresponds to $-\delta m^2 \hat{f}^2$ at the IR quasi-fixed point discussed above, while the second accounts for the running between $M$ and $m_{\tilde{H}}$. One should note that in reaching the quasi-fixed point value, the explicit loop suppression factor is lost,

\(^{15}\)In addition to the modification of the running of the Yukawa coupling, there is a correction to the $\beta$ function for $\mu_{\text{eff}}$ (see App. E).

\(^{16}\)A more precise treatment will identify the relevant thresholds and integrate out the respective degrees of freedom accordingly in order to identify the pNGB mass parameter at the weak scale. In this work we will be satisfied with the leading approximation that does not take into account such subtleties.
Figure 3. RG flow of the ratio $\delta m^2/\mu_{\text{eff}}^2$ and $\xi$. The dashed line marks the exact IR fixed point $-r_*$ that is reached in the absence of gauge interactions, the solid blue line is the asymptotic trajectory including QCD effects. The dots on the trajectories represent e-folds of RG running.

and the size of this contribution to the pNGB Higgs mass parameter is controlled by $\mu_{\text{eff}}$. We should find that the explicit RG scale-dependence in Eq. (3.6) precisely accounts for the running of $\mu_{\text{eff}}^2$ and the field rescaling of $\mathcal{H}$. Indeed, from Eq. (3.4) and Eq. (E.1) one finds

$$\frac{\beta \mu_{\text{eff}}^2}{\mu_{\text{eff}}^2} - 2\gamma_\Phi = - \frac{11}{16\pi^2} \xi^2.$$  \hspace{1cm} (3.7)

$M$ can be chosen at will as long as the running parameters are evaluated at that scale. It is thus natural to choose $M \sim m_H$, in which case the parenthesis in Eq. (3.6) is close to one. The finite pieces of $\alpha$ and the corresponding contribution to $\beta$ are given in App. C.

We remark that the modification needed for the minimal model (in which the hypercharge $1/6$ resonance is decoupled) is simply to replace $\mu_{\text{eff}}$ by

$$\tilde{\mu}_{\text{eff}}^2 \equiv 2\mu_{tS}^2 - \mu_{QQ}^2 ,$$  \hspace{1cm} (3.8)

whereas Eq. (3.4) and hence the value of $r_*$ remain unchanged, as the decoupled state $(q_L, Q^1_R)$ does not possess any Yukawa interactions.
4 Electroweak Symmetry Breaking and the Higgs Mass

Our starting point is the parametrization of the Higgs potential in the approximation of Eq. (3.1). EWSB and the correct Higgs mass imply the following simple conditions:

\[
\alpha = \frac{m_h^2 f^2}{2 c_v^2} \approx \frac{(88 \text{ GeV})^2 f^2}{c_v^2}, \quad \beta = \frac{m_h^2 f^2}{2 c_v^2 s_v^2} \approx \frac{0.13 f^4}{c_v^2},
\]

(4.1)

Notice that the Higgs VEV \( v = \langle h \rangle \) is not equal to the SM model value \( v_{SM} = 246 \text{ GeV} \) but is rather fixed by the relation \( s_v f = v_{SM} \).

A crucial observation that will facilitate the discussion below is that one has to expect a certain degree of cancellation between the different contributions to Eq. (3.3). Observe that the leading contribution to \( \alpha \) arises from Eq. (3.6) and is given by

\[
\frac{\alpha}{f^2} = r_\ast \mu_{\text{eff}}^2 r_v^{-1} + \ldots,
\]

(4.2)

The parameter \( \mu'_{QQ} \) equals the mass \( m'_Q \) of the exotic doublet \( Q^2 \) and it is already constrained by direct LHC searches of strongly pair-produced \( Q = 5/3 \) fermions to be larger than about 800 GeV at 95% C.L. [54].\(^{17} \) However, if \( \mu_{\text{eff}} \) was of that size, then its contribution would need to be canceled by other (truly loop-suppressed) contributions, which requires large couplings \( g_\rho, \xi \), possibly outside the perturbative regime. One thus expects a certain degree of cancellation to happen between the different terms in \( \mu_{\text{eff}}^2 \) such that \(^{18} \)

\[
|\epsilon| \ll 1, \quad \text{where} \quad \epsilon \equiv \frac{\mu_{\text{eff}}^2}{2 \mu_{tS}^2}.
\]

(4.3)

To reasonably good approximation one can thus set \( \mu_{\text{eff}} \approx 0 \) everywhere but in the leading contribution to \( \alpha_{1/2} \) given by Eq. (4.2) (for instance, we can approximate \( \beta_{1/2} \approx \beta_{1/2}|_{\mu_{\text{eff}}=0} \)). In the minimal model, the same argument leads one to conclude that

\[
|\tilde{\epsilon}| \ll 1, \quad \text{where} \quad \tilde{\epsilon} \equiv \frac{\tilde{\mu}_{\text{eff}}^2}{2 \mu_{tS}^2}.
\]

(4.4)

We will make use of these relations in the discussions below, but will always keep the exact expressions in our numerical analyses.

We will start our analysis with the minimal scenario described in Section 2.2, and first consider the case with vanishing tadpole. Using then Eq. (4.4) in the expression for the

\(^{17}\)The lower limits for \( Q = 2/3 \) top-partners are around 700 – 800 GeV, depending on the decay mode [55, 56], while \( Q = -1/3 \) fermionic resonances should be heavier than about 500 – 800 GeV [57]. See also [58].

\(^{18}\)Notice that as \( \mu_{\text{eff}} \) renormalizes only multiplicatively this is a technically natural tuning. We come back to the issue of naturalness in Section 5.
(dominant) fermionic contribution to $\beta$, one obtains

$$\frac{\beta_{1/2}}{f^4} = \frac{3}{4\pi^2} \frac{m^4}{v^4_{\text{SM}}} \left( \log \frac{m^2_Q}{m^2_t} - \frac{r_f^2(3-r_f')}{(1-r_f')^3} \log r_f' - \frac{1+r_f'^2}{(1-r_f')^2} \right)$$

$$\leq \frac{3}{4\pi^2} \frac{m^4}{v^4_{\text{SM}}} \left( \log \frac{m^2_Q}{m^2_t} - 1 \right). \quad (4.5)$$

where the upper bound in the second line is attained for $r_f' \to 0$. This is too small and, comparing to Eq. (4.1), implies that the correct Higgs mass cannot be achieved unless $c_v \approx 1$ (e.g. $f > 1$ TeV) and $m_{Q'} \gtrsim 1.7$ GeV (using the exact expressions, the situation is actually worse, and typically we find too light a Higgs). A very similar conclusion is reached for the extended model with the $SO(4)$ symmetric choice $\mu_{QQ} = \mu_{Q'Q}$. In this case Eq. (4.3) reduces $\beta_{1/2}$ to the same expression, Eq. (4.5), with the replacement $r_f' \to r_f, m_{Q'} \to m_Q$ and hence

$$\frac{\beta_{1/2}}{f^4} \leq \frac{3}{4\pi^2} \frac{m^4}{v^4_{\text{SM}}} \left( \log \frac{m^2_Q}{m^2_t} - 1 \right). \quad (4.6)$$

A possible solution to this problem is to add the explicit $SO(5)$ breaking tadpole term, Eq. (2.17), which easily accounts for the missing contribution to $\beta$. One obtains

$$\alpha_\tau = -\tau \hat{f}, \quad \beta_\tau = \frac{1}{2} \tau \hat{f}. \quad (4.7)$$

As $\beta_{1/2} + \beta_1$ is positive but too small, $\tau$ needs to be positive but is bounded from Eq. (4.1) by

$$\tau \lesssim 0.26 \frac{f^4}{f c_v^2}, \quad (4.8)$$

In particular, the correction to the mass of the radial mode due to the tadpole, cf. Eq. (2.18), is negligible. Moreover the relation (4.3) remains true, as $\alpha_\tau$ can never become large enough so as to significantly reduce the leading contribution to $\alpha$.

However, as it turns out, the fermionic contribution to the $T$ parameter is negative in the minimal model, for reasons closely connected to those first discussed in [59]. As we have already pointed out at the end of Section 2.3, this means that EWPT are very difficult to satisfy. In fact, performing a scan of the minimal model over 3000 points with $0.5$ TeV < $f$ < 2 TeV, we find not a single point within 95% C.L., and only 20 points pass EWPT at 99% C.L. (see the left panel of Fig. 4).\(^{19}\)

A next to simplest model is the extended model with $\mu_{QQ} = \mu_{Q'Q}$, and $\tau > 0$ to raise the Higgs mass. This model has the interesting feature that the tuning Eq. (4.3) is protected, as the point $\mu_{QQ} = \mu_{Q'Q} = \mu_{tS}$ is invariant under the global symmetry. However, as with the

\(^{19}\)Here and in the following we also include an additional contribution to the $T$ parameter $\Delta T = -\frac{3}{8\pi} \frac{m_h^2}{m_W^2} \log \frac{\Lambda}{m_h}$ due to modified Higgs couplings [60]. For definiteness we use $\Lambda = m_\rho$ in our scans.
Figure 4. Electroweak precision tests for the minimal model with $\tau \neq 0$ (left) and the extended model with $\mu_{QQ} = \mu'_{QQ}$ and $\tau < 0$ (right). We scan over the ranges $f \in [500, 2000]$ GeV, $r_v \in [0.05, 0.95]$, $g_\rho \in [0, 3\pi]$, $s_R \in [0, 1]$ (and, for the right plot, $s_L \in [0, 1]$). We fix $\tau$, $m_S$ and $m_Q$ from EWSB (Higgs vev and Higgs mass) plus the top mass, but requiring $m_S, m_Q > 500$ GeV. In the left panel we also require $|\tau| \in [0, (1000 \text{ GeV})^3]$ while in the right panel we impose $\tau \in [-3000 \text{ GeV}^3, 0]$. All points reproduce the correct Higgs, top and $Z$ masses. The contours correspond to 68%, 95% and 99% C.L. respectively [53].

minimal scenario, for $\tau > 0$ all points that lead to successful EWSB have a negative $T$ and do not pass EWPT. There exists however a possibility in the latter scenario to accommodate both the correct Higgs mass and EWPT with a large negative value for $\tau$. In fact, if $-\tau$ is so large as to cancel a large negative $\mu_{\text{eff}}^2$, we can escape the condition (4.3) and $\beta_{1/2}$ is not bounded by (4.6). This will however require a very large $|\tau|$, and both $\alpha$ and $\beta$ show substantial cancellations between tadpole and other contributions. Notice that a large negative $\tau$ is bounded by the mass for the radial mode, Eq. (2.18). We show the $S$ and $T$ parameters of this model in the right panel of Fig. 4. We find that the interplay of EWSB and EWPT require in this case a peculiar hierarchy of fermion masses, $m_S < m'_Q < m_Q$.

The correct Higgs mass and agreement with EWPT can also be achieved in the extended model with $\mu_{QQ} \neq \mu'_{QQ}$ (see Fig. 5). As this introduces a new source of explicit $SO(4)$ violation, we expect the $T$ parameter to be affected. We first consider the case $\tau = 0$. As we already pointed out above, at $\mu_{QQ} = \mu^2_{QQ}$, $\beta_{1/2}$ is bounded by Eq. (4.6), resulting in a too small Higgs mass. One can show that $\beta$ can be raised if

$$
(\mu^2_{QQ} - \mu'^2_{QQ})(\mu^2_{QQ} + \mu'^2_{QQ} - \mu^2_{QQ}) > 0,
$$

which implies that either $\mu_{QQ} > \mu'_{QQ}$ or $m_Q < m'_Q$. It turns out that the former case further
Figure 5. Electroweak precision tests (left) and fermion spectrum (right) for the extended model with $\mu_{QQ} \neq \mu'_{QQ}$. The plots in the upper row assume vanishing tadpole, while those in the lower row have a positive tadpole term. For $\tau > 0$, we also impose $m_Q < m'_Q$. We scan over the ranges $f \in [500,2000]$ GeV, $\rho_v \in [0.05,0.95]$, $g_\rho \in [0,3\pi]$, $s_R \in [0,1]$ and $s_L \in [0,1]$. In the plots of the upper row, we fix $m_S, m_Q$ and $m'_Q$ from EWSB (Higgs vev and Higgs mass) plus the top mass, but requiring $m_S,m_Q,m'_Q > 500$ GeV. In the lower row plots we instead fix $\tau$, $m_S$ and $m_Q$ from EWSB plus the top mass, requiring $m_S,m_Q > 500$ GeV, while scanning over $m'_Q \in [500,3000]$ GeV and fixing $f = 500$ GeV. The blue points pass EWPT at 95% C.L.
The ratio \( m_\rho/m_a = \sqrt{r_v} \) is held fixed, with \( r_v = 0.9, 0.75 \) and 0.5 (from top to bottom). Right panel: amount of explicit violation of the global and custodial symmetries, as parametrized by the quantities \( \epsilon \) and \( a_\mu \), for the same parameter scan as in the lower row plots of Fig. 5. All points reproduce the correct Higgs, top and Z masses. The blue points pass EWPT at 95% C.L.

finally, we also performed a full scan of the extended model with \( \mu_{Q\bar{Q}} \neq \mu'_{Q\bar{Q}} \) with nonzero tadpole term (see plots in the lower row of Fig. 5). We only discuss in detail the case \( \tau > 0 \). The implications for the spectrum are similar as in the case with \( \tau = 0 \), with the difference that the states can generally be lighter while still passing EWPT. We present
in the lower row plots of Fig. 5 a scan with fixed $f = 500$ GeV, with the fermion masses in the range $\{500, 3000\}$ GeV. In addition we require $m_Q < m_Q'$ as otherwise $T$ is negative.

It is also interesting to know how much explicit violation of the global symmetry is required in the fermionic mass Lagrangian. We therefore plot in the right panel of Fig. 6 the quantity $\epsilon$ defined in Eq. (4.3) against the asymmetry parameter

$$ a_\mu \equiv \frac{\mu_Q' - \mu_Q}{\mu_Q' + \mu_Q}. \tag{4.11} $$

The point $\epsilon = a_\mu = 0$ corresponds to the $SO(5)$ preserving choice $\mu_{QQ} = \mu_{QQ}' = \mu_{tS}$, while the deviations from $a_\mu = 0$ parametrize the breaking of the custodial symmetry in the “composite sector”, to use the language of Section 2.2. We see that $a_\mu \gtrsim 0.15$ is required in order to obtain points that pass EWPT, while $\epsilon$ is always very small as expected from the general arguments above.

We summarize the various scenarios studied in this section in the following table:

| Model      | $m_h$ | EWPT | Spectrum | Remarks          |
|------------|-------|------|----------|------------------|
| Minimal    |       |      |          |                  |
| $\tau = 0$ | too light | ✓    | x        |                  |
| $\tau \neq 0$ | ✓      |      |          |                  |
| Extended   |       |      |          |                  |
| $\mu_{QQ} = \mu_{QQ}'$ |       |      |          |                  |
| $\tau > 0$ | ✓      | ✓    | x        | $m_H < m_S < m_Q' < m_Q$ $\epsilon \ll 1$ |
| $\tau < 0$ | ✓      | ✓    | ✓        | $m_Q < m_Q', m_S$ $\epsilon \ll 1$ |
| $\mu_{QQ} \neq \mu_{QQ}'$ |       |      |          |                  |
| $\tau > 0$ | ✓      | ✓    | ✓        | $m_Q < m_Q', m_S$ $\epsilon \ll 1$ |
| $\tau < 0$ | ✓      | ✓    | ✓        |                  |

Table 2. Summary of our various scenarios. In the last column we have defined $\epsilon = \mu_{eff}^2/2\mu_{tS}^2$. See text for details.

### 5 Naturalness Considerations

Indirect constraints from electroweak precision data as well as direct bounds on vectorlike top partners will require a sufficiently high scale for the global symmetry breaking, resulting in a certain fine-tuning of parameters. In order to get a first idea, it is enough to notice that the largest cancellation occurs in the quantity $\alpha$. There will be a large positive contribution proportional to $\mu_{tS}^2$, leading to a sensitivity

$$ \frac{\Delta \alpha_{\mu_{tS}}}{\alpha} \approx \frac{4r_s \mu_{tS}^2}{r_v m_h^2}. \tag{5.1} $$

For $\mu_{tS} = 500$ GeV and $r_v = 0.5$ this implies a tuning of about 1%.
In the following we will quantify these considerations more precisely by evaluating the
sensitivity parameter
\[ \Delta M \equiv \max_P \Delta^M_P , \quad \Delta^M_P \equiv \frac{\left| \partial \log M \right|}{\partial \log P} , \]
where \( M \) runs over the measured quantities \( M \in \{ v^2, m_h^2, m_t^2 \} \) and \( P \) over the parameters of the model. It is important to pick a basis for \( P \) that corresponds to the parameters in the Lagrangian. We thus chose
\[ P \in \{ \hat{f}, f_\rho, \xi, g_\rho, \mu_{tS}, \mu_{QQ}, \mu_{QQ'}, \tau \} . \]

One can easily evaluate
\[
\Delta v^2 = \left| \frac{f s_v}{v c_v} \partial_p \log \frac{\alpha}{\beta} + \partial_p \log f^2 \right| , \quad \Delta^2_{m^2} = \left| \partial_p \log \frac{\alpha}{f^2} - \frac{s_v}{c_v} \partial_p \log \frac{\alpha}{\beta} \right| , \quad \Delta_{m^2} = \left| \partial_p \log \frac{\alpha \gamma}{\beta} \right| ,
\]
where \( p = \log P \) and \( \gamma = \xi^2 \hat{f}^2 \mu_{tS}^2 \mu_{QQ}^2 / m_S^2 m_Q^2 \). All of the \( \Delta^M \) in Eq. (5.4) are dominated by \( \partial_p \log \alpha \), and it turns out the largest one is \( \Delta v^2 \). We plot the latter in the left panel of Fig. 7, using the same parameter scan as in the lower row plots of Fig. 5. We find that the maximal sensitivity is to the parameter \( \mu_{tS} \) for all points, and pretty much follows the general considerations in Eq. (5.1), shown as the gray band in the plot. The cancellation of the term proportional to \( \mu_{tS}^2 \) then typically requires fine tuning below 1%.

However, as we already discussed in Section 4, to some extent this cancellation must happen against the other terms in \( \mu_{\text{eff}} \), as the other contributions to \( \alpha \) are loop suppressed,
and the quantity $\epsilon$ defined in Eq. (4.3) is expected to be small. In the vicinity of the point $\mu_S = \mu_{QQ} = \mu'_{QQ}$ this cancellation is protected by the global symmetry, as except for the mixing term $\mu_{qQ}$ the fermion mass Lagrangian becomes $SO(5)$ symmetric.\footnote{See the right panel of Fig. 6 for the required amount of $SO(5)$ violation.} However, even away from this point, $\mu_{\text{eff}}$ only renormalizes multiplicatively and one can thus consider this tuning "technically natural". One could thus ask the question of how much tuning is required beyond the one needed in order to obtain small $\epsilon$. This question can be answered by evaluating again the same sensitivity parameters, but with $\mu_{\text{eff}}$ held fixed, i.e. we replace
\begin{equation}
\partial_p \rightarrow \partial_p|_{\mu_{\text{eff}} \text{ fixed}}.
\end{equation}
The result is plotted in the right panel of Fig. 7. As expected, the tuning is considerably reduced, as large as 5% for the points that pass EWPT. The largest sensitivity occurs with respect to the parameters $g_\rho$ and $\mu'_{QQ}$.

We now return to theoretical considerations in order to close a possible loophole on how to obtain the set of four-fermion operators used thus far.

\section{A Simple Model leading to $SO(N)$ Symmetric 4-Fermion Interactions}

We pointed out in Subsection 2.1 that four-fermion interactions naturally lend themselves to the implementation of $SO(N)$ symmetries, as opposed to $SU(N)$ symmetries. In particular, when $G_S \neq G'_S$ in Eq. (2.4), the global symmetry of the theory is $SO(N)$ and one can work in a region of parameter space where the only light states are those of the $SO(N) \to SO(N-1)$ breaking. In this section we describe a simple renormalizable model that can lead to the above situation.

Consider a $SU(N_c) \times SU(N_c)$ gauge theory, and assume that the fermions described in Subsection 2.1, $F_{\ell}^i$ and $S_R$, transform in the $(N_c, 1)$ representation. We assume that this gauge symmetry is (spontaneously) broken, as in top-color UV completions \cite{top-color} of the top condensation mechanism \cite{top-condensation}. The diagonal $SU(N_c)$, with $N_c = 3$, is then identified with the QCD interactions,\footnote{We imagine that all matter is charged under the first $SU(3)$ group only. Since the full model consists of the SM field content plus additional vectorlike states, the theory is easily seen to be vectorlike with respect to $SU(3) \times SU(3)$, hence anomaly free.} while the broken $SU(N_c)$ induces four-fermion operators below the mass of the corresponding gauge boson, $G_{\mu}$. In addition, assume there exists a real scalar field $\Xi$ that transforms in the fundamental representation of the “flavor” $SO(N)$, as does $F_{\ell}^i$, while being a singlet of the new gauge group. In unitary gauge, one can then write the following terms in the UV Lagrangian:

\begin{equation}
\mathcal{L}_{\text{UV}} \supset -\frac{1}{2} M_\Xi^2 \Xi^2 + y (\bar{S}_R \Xi F_{\ell}^i + \text{h.c.}) + \frac{1}{2} M_G^2 G_{\mu} G^{\mu} + \frac{1}{2} \hat{g} G_{\mu}^A (\bar{S}_R \gamma^\mu \lambda^A S_R + \bar{F}_{\ell}^i \gamma^\mu \lambda^A F_{\ell}^i),
\end{equation}

\begin{equation}
(6.1)
\end{equation}
where $\lambda^A$ are the Gell-Mann matrices. The contractions of the indices not explicitly shown should be obvious. We have assumed above, for simplicity, that the Yukawa coupling, $y$, is real. Integrating out the heavy gauge and scalar fields, leads to an effective Lagrangian

$$\mathcal{L} \supset \frac{y^2}{2M^2_\Xi} (\bar{S}_R F^i_L + \text{h.c.})^2 - \frac{\hat{g}^2}{8M^2_G} (\bar{S}_R \gamma^\mu \lambda^A S_R + \bar{F}_L i \gamma^\mu \lambda^A F^i_L)^2$$

$$= \frac{y^2}{2M^2_\Xi} (\bar{S}_R F^i_L + \text{h.c.})^2 - \frac{\hat{g}^2}{4M^2_G} (\bar{S}_R \gamma^\mu \lambda^A S_R)(\bar{F}_L i \gamma^\mu \lambda^A F^i_L) + \cdots,$$

where the terms not shown correspond to vector channels and are further discussed in App. A. Upon Fierz rearrangement of the second term, and neglecting further vector channels, one gets

$$\mathcal{L} \supset \frac{y^2}{2M^2_\Xi} (\bar{S}_R F^i_L + \text{h.c.})^2 + \frac{\hat{g}^2}{M^2_G} (\bar{S}_R F^i_L)(\bar{F}_L i S_R) + \cdots.$$

This can be written as $\mathcal{L}_S + \mathcal{L}'_S$ of Eq. (2.4) with the identifications

$$G_S = \frac{\hat{g}^2}{2M^2_G} + \frac{y^2}{M^2_\Xi} , \quad G'_S = \frac{\hat{g}^2}{2M^2_G}.$$

We see that the splitting between $G_S$ and $G'_S$ [hence the explicit breaking from $SU(N)$ down to $SO(N)$] is controlled by the heavy scalar sector [which is not surprising given that $\Xi$ is the only field that transforms explicitly only under $SO(N)$]. In addition, we see that the effective coupling $G_S$ is positive and naturally larger than $G'_S$, as required in Subsection 2.1. We conclude that it is not far-fetch to have $G_S$ close to criticality (through some degree of tuning, as is typical in the context of the NJL mechanism), while $G'_S$ is sub-critical so that the corresponding (irrelevant) four-fermion operators play no role at low energies.

One should note that the scalar field $\Xi$ enters in a very similar fashion to the scalar $\Phi$ of Subsection 2.1. However, these d.o.f. are distinct and should not be confused. Whereas the scalar $\Xi$ above is a propagating degree of freedom, with a well-defined kinetic term above scales of order $G_S^{-1/2}$, the scalar $\Phi$ discussed in the main text is a $(\bar{F}_L S_R)$ bound state, that exists as such only well below the scale $G'_S^{-1/2}$. While the two scalars share the same quantum numbers, they are better thought as “dual” to each other, in the sense of UV versus IR degrees of freedom. Having said this, it is possible that the scalar $\Xi$ is itself a composite that arises in the process of breaking the $SU(N_c) \times SU(N_c)$ gauge symmetry and whose mass is tied to that of the gauge field $G_\mu$. Since for our applications $\Xi$ can have a mass of a similar order as that for $G_\mu$ (but with no special relation), we see that no tuning beyond the one required to lie close to criticality needs to be imposed in this new scalar sector.

### 7 Conclusions

One of the major questions whose answer will determine qualitatively the nature of physics near the weak scale is whether the Higgs resonance identified by the ATLAS and CMS
collaborations \[1, 2\] is elementary down to ultra-short distances or whether it is actually a composite state of more fundamental constituents, whose nature could be revealed at energies not far above the EW scale. In either case, a phenomenon never seen in nature before would have been established. In the first case, we would have discovered the first example of an “elementary” scalar, which perhaps could suggest the presence of supersymmetry at some higher scale (given that fundamental scalars are a generic prediction of supersymmetric scenarios). If, on the other hand, the Higgs turned out to be composite, it would be the first example of condensation by such a scalar that can be effectively described by weakly coupled dynamics. In spite of this, its composite nature itself would point to some strongly coupled underlying dynamics that, if realized by nature, would lead to a qualitatively different view of the EW scale than in the first case.

In this work we have explored a possible microscopic realization of the second possibility, modeling the interactions that lead to the scalar bound state via four-fermion interactions à la NJL \[19, 20\]. This allows the explicit identification of the Higgs constituents and the interactions responsible for the formation of the bound states. As was first done in Ref. \[23\], in order to obtain a scalar resonance that is parametrically lighter than other strong resonances, it is assumed that the microscopic Lagrangian possesses an approximate global symmetry that is spontaneously broken by the NJL mechanism, thus leading to suitable Nambu-Goldstone bosons, some of which can be identified with the Higgs. In order to control potentially large corrections to precision EW measurements, we implement a scheme that preserves approximately a custodial symmetry, as well as the custodial symmetry protection of the \[Zb\bar{b}\] coupling put forward in \[30\] (a similar setup to ours was studied in \[27\]). As is well known, minimality together with the above requirements uniquely singles out the symmetry breaking pattern \[SO(5) \rightarrow SO(4) \approx SU(2)_L \times SU(2)_R\]. In addition, the SM \[b_L\] satisfies \[T_3^L = T_3^R\].

We point out here that four-fermion interactions naturally lend themselves to implementing the above symmetry breaking pattern. Unlike fermion bilinears\[22\] which typically preserve an \(SU(N)\) symmetry, for four-fermion operators it is possible to impose a reality condition that preserves only the \(SO(N)\) subgroup. We also point out that in the context of the NJL mechanism, the breaking by the 4-fermion interactions from \(SU(N)\) down to \(SO(N)\) may be small, yet effective: if one is close to criticality, small effects can easily make the additional \(SU(N)\) resonances much heavier than those associated with the \(SO(N)\) breaking. We have provided a simple UV complete model (potentially up to the Planck scale) that realizes our framework. In this respect, our implementation represents a considerable simplification with respect to the schemes proposed in \[23, 27\].

Also, unlike the previous works, we have explicitly described the spin-1 sector that would be responsible for the cancellation of the quadratic divergences in the Higgs mass arising from the SM gauge interactions. We have highlighted the qualitative differences\[22\]Kinetic terms and gauge interactions. Mass terms can in principle reduce the symmetry appropriately. However, in our minimal implementations this is not an option.
between the spin-1 and scalar sectors in terms of calculability. We have paid particular
attention to the fermion sector with an eye towards minimality, emphasizing the role played
by the new degrees of freedom beyond the SM. Importantly, we find that the presence of
quasi-fixed points (generalizing the observations in [15]) imply that the low-energy physics
is largely insensitive to uncertainties arising from the underlying strong dynamics.

Given the presence of four-fermion interactions that, through the NJL mechanism,
break $SO(5) \to SO(4)$, we recover at low energies the SM field content, except that the
Higgs potential is dynamically induced and the breaking of the EW symmetry (or not)
is an outcome of the theory. We have shown that in regions of parameter space where
the EW symmetry is actually broken, it is possible to accommodate the observed Higgs
mass of about 125 GeV [62, 63]. In some cases, this requires turning on a tadpole term
(equivalent to a certain vector-like fermion mass), but we have also identified cases where
such a tadpole is not essential. We find, however, that in general there is some tension
with EW precision measurements. This is due to a typically negative contribution to the
Peskin-Takeuchi [33] $T$-parameter that arises from two sources: the non-linear couplings of
the Higgs field to the gauge bosons, due to its pNGB nature [60], and the fermion loop
contributions. The latter effect is tied to the imposed custodial protection (on $T$ and $Zb\bar{b}$)
which suppresses the contributions to an acceptable order of magnitude, but typically leads
to a negative sign that makes agreement with the $S - T$ ellipse challenging. Such an effect
has the same origin as first pointed out in the context of extra-dimensional constructions
in [59]. Interestingly, in our setup it is possible to allow for a controlled amount of custodial
breaking in the heavy fermion sector so that the corresponding contribution to $T$ changes
sign and allows compatibility with EWPT. We emphasize that this custodial breaking is
soft, so that the effects are fully calculable within the theory, and no particular tuning of
parameters is required. Nevertheless, well-defined regions of parameter space are selected in
this way, which have implications for the expected hierarchies of states beyond the SM ones.

We have also studied the tuning in the present models, as measured by the sensitivity
of low-energy observables to UV Lagrangian parameters. Without any special assumptions
about the UV, the tuning so defined is found to be at the percent level or worse. Interestingly,
however, this tuning has a rather well-defined source throughout the region of parameter
space. It arises from a necessary cancellation between fermion mass parameters, forced by
current LHC direct lower bounds on some of these states. However, the region corresponding
to such a cancellation actually corresponds to an enhanced symmetry point of the theory.
Therefore, small deviations from perfect cancellation can be naturally small, in the ’t Hooft
sense. The remnant fine-tuning (assuming the previous cancellation between fermion mass
parameters) can be on the order of $1 - 5\%$.

The model we have described contains a rather minimal set of fields beyond those of
the SM. In the fermion sector, we have a vectorlike 5 of $SO(5)$, which decomposes into a
bi-doublet of $SO(4) \approx SU(2)_L \times SU(2)_R$ [the states $Q$ and $Q'$ with approximate masses
$m_Q$ and $m'_Q$, as given in Eqs. (2.20) and (2.23)] plus a singlet $S$ with approximate mass as
given in Eq. (2.20). Hence, we have three top-like partners, a $b'$ and an exotic $Q = 5/3$
state, as is common in many CH model with a custodial protection of $Zb\bar{b}$. Several search strategies to look for such states at the LHC have been put forward (see, for instance, [58], and references therein), and a number of LHC searches already exist which can be sensitive to such states below about 800 GeV [54–57]. We have found that typically $m_Q < m'_Q, m_S$.\textsuperscript{23} Direct searches, in particular those for $Q = -1/3$ and $Q = 2/3$ states (in our case arising from the $Q$ state), imply within our model that $m_S \gtrsim 1.6$ TeV (although it may well be significantly heavier), while EWPT require $m'_Q \gtrsim 1$ TeV (which corresponds to the mass of the $Q = 5/3$ state).

In addition to the fermion sector above, we predict the existence of a “radial” Higgs mode, $H$, that together with the pNGB degrees of freedom form a 5 of $SO(5)$. When the tadpole term can be neglected, the mass of $H$ is less than about 4/3 of the singlet fermion mass $m_S$. Such a scalar state would likely be beyond the reach of the LHC, but might be accessible at a 100 TeV collider. We defer this issue to future work. Finally, there are spin-1 resonances that, however, cannot be guaranteed to lie below the cutoff of the theory, where the composite Higgs “dissolves” into its constituents. The gap between this cutoff scale and $m_H$ depends on how close to criticality is the (scalar channel) four-fermion coupling. Near this cutoff scale, there may exist further excited resonances of various spins. We have, however, noted that above this scale the UV degrees of freedom may be relatively few, and described by a renormalizable theory, perhaps valid up to much higher energies. It would be interesting to study the implications of such a scenario at a future high-energy facility.

We end by noting that we have focused our attention on the third generation, which is likely to be most relevant for EWSB. However, accommodating the first two generations, and understanding how issues such as the flavor structure could be embedded in the present framework would be of extreme interest, and are likely to provide further handles from precision flavor measurements, rare decays or CP-violation.

A Four-fermion Interactions from Vector Boson Exchange

In this appendix we rewrite the four-fermion interactions induced by heavy vector boson exchange in the model of Section 6. Our purpose is to identify the full set of scalar and vector channels thus generated (the scalar ones were presented in the main text). For this purpose, it will be useful to recall the following generic Fierz rearrangement for the vector

\textsuperscript{23}Although in the presence of a very large tadpole, Eq. (2.17), one can have the peculiar hierarchy $m_S < m'_Q < m_Q$. In this case, all states would be rather heavy.
channel
\[
(\bar{\alpha} \gamma^\mu B)(\bar{C} \gamma_\mu D) = -(\bar{A} D)(\bar{C} B) + (\bar{A} \gamma^5 D)(\bar{C} \gamma^5 B) + \frac{1}{2} \left[ (\bar{A} \gamma^\mu D)(\bar{C} \gamma_\mu B) + (\bar{A} \gamma^5 \gamma^\mu D)(\bar{C} \gamma^5 \gamma_\mu B) \right],
\]

as well as the “color” identity
\[
(\bar{\chi}_i \Gamma^i \chi_j)(\bar{\psi}_j \Gamma^j \psi_i) = (\bar{\chi}_i \Gamma^i t^A \chi_i)(\bar{\psi}_j \Gamma^j t^A \psi_j) + \frac{1}{N_c} (\bar{\chi}_i \Gamma^i \chi_i)(\bar{\psi}_j \Gamma^j \psi_j),
\]

where \(\Gamma\) is any set of gamma matrices that makes \(M_{ij} = (\bar{A}_i \Gamma A^j)\) hermitian, while \(i, j\) are \(U(N)\) indices. Here and in the following we normalize the \(SU(N)\) generators as \(\text{tr} t^A t^B = \delta^{AB}\).

In the following, we denote by \(i\) (I) the fundamental (adjoint) index of \(SU(N_L)\), and by \(a\) (A) the fundamental (adjoint) index of \(SU(N_c)\). We focus on the fermion field content of Section 6, \(F^a_{L,i}\) and \(S^a_R\), so that, for example,
\[
\frac{1}{2} (\bar{F}_L \gamma^\mu \lambda A^i F_L)^2 = (\bar{F}_{L,a} \gamma^\mu F^b_L)^2 - \frac{1}{N_c} (\bar{F}_L \gamma^\mu F_L)^2
\]
\[
= (\bar{F}_{L,i} \gamma^\mu F^i_L)^2 - \frac{1}{N_c} (\bar{F}_L \gamma^\mu F_L)^2
\]
\[
= (\bar{F}_L \gamma^\mu T^i F_L)^2 + \left( 1 - \frac{1}{N_L} \right) (\bar{F}_L \gamma^\mu F_L)^2,
\]

where \(T^i\) are the generators of \(SU(N_L)\). Here we have used a condensed notation where the color and flavor indices in \(F^a_{L,i}\) that are not shown explicitly are understood to be appropriately contracted between the fields within each factor in parenthesis.

Analogously for the RH field \(S^a_R\) we find
\[
\frac{1}{2} (\bar{S}_R \gamma^\mu \lambda S_R)^2 = \left( 1 - \frac{1}{N_c} \right) (\bar{S}_R \gamma^\mu S_R)^2,
\]

while for the mixed term one obtains
\[
\frac{1}{2} (\bar{S}_R \gamma^\mu \lambda A^i S_R)(\bar{F}_L \gamma^\mu \chi^A F_L) = (\bar{S}_{R,a} \gamma^\mu S^b_R)(\bar{F}_{L,b} \gamma^\mu F^a_L) - \frac{1}{N_c} (\bar{S}_R \gamma^\mu S_R)(\bar{F}_L \gamma^\mu F_L)
\]
\[
= -2(\bar{S}_R F^a_L)(F_{L,i} S_R) - \frac{1}{N_c} (\bar{S}_R \gamma^\mu S_R)(\bar{F}_L \gamma^\mu F_L),
\]

where the first term reproduces the scalar channel written in Eq. (6.3). Putting everything together one concludes that the exchange of the heavy vector bosons \(G_\mu\) induces the following
set of four-fermion interactions:

\[
\frac{1}{2} \left( \bar{S}_R \gamma_\mu \lambda^4 S_R + \bar{F}_L \gamma_\mu \lambda^4 F_L \right)^2 = -4(\bar{S}_R F_L^i)(\bar{F}_{L,i} S_R) + (\bar{F}_L \gamma_\mu T_I F_L)^2 
- \frac{1}{N_c} (\bar{S}_R \gamma_\mu F_R + \bar{F}_L \gamma_\mu F_L)^2 + \frac{1}{N_L} (F_L \gamma_\mu F_L)^2 + (\bar{S}_R \gamma_\mu S_R)^2 
= -4(\bar{S}_R F_L^i)(\bar{F}_{L,i} S_R) + (\bar{F}_L \gamma_\mu T_I F_L)^2 
+ \left( \frac{1}{4N_L} + \frac{1}{4} - \frac{1}{N_c} \right) J_+^2 + \left( \frac{1}{4N_L} + \frac{1}{4} \right) J_-^2 + \left( \frac{1}{2N_L} - \frac{1}{2} \right) J_+ J_-(A.6)
\]

where we defined

\[
J_{\pm, \mu} \equiv (\bar{F}_L \gamma_\mu F_L \pm \bar{S}_R \gamma_\mu S_R) .
\]

We see that apart from the scalar channel discussed in Section 6, the topcolor interactions also produce a vector \( SU(N_L) \) channel that contains the \( SO(N_L) \) channel of Eq. (2.29) [with the correct sign required in the discussion around Eq.(2.29)]. There are also \( U(1) \) currents that, however, do not exactly match the \( U(1)_X \) current of Eq. (2.30). Had we included \( N_R \) flavor \( S^a_{R,i} \), the last line in Eq. (A.6) would have read

\[
\left( \frac{1}{4N_L} + \frac{1}{4N_R} - \frac{1}{N_c} \right) J_+^2 + \left( \frac{1}{4N_L} + \frac{1}{4N_R} \right) J_-^2 + \left( \frac{1}{2N_L} - \frac{1}{2N_R} \right) J_+ J_-(B.1)
\]

The condition for the eigenvalues of this system to be both positive is \( N_c > N_L + N_R \). The condition for \( J_+ \) and \( J_- \) to be eigenstates is \( N_L = N_R \). For \( N_c = 3 \) and the flavor content we have in mind, there is always one negative and one positive eigenvalue. The “wrong sign” four-fermion interaction would then correspond to a repulsive channel that does not lead to spin-1 bound states. At any rate, as we remarked in the main text, the \( U(1)_X \) resonance leads only to subleading modifications when \( g_X^2 \gg g_0^2 \). Therefore, for our purposes the microscopic model introduced in Section 6 is sufficient to establish the possibility of UV completing our point of departure in the main text.

**B \ SO(5) Basis**

The Minimal Composite Higgs literature based on the coset space \( SO(5)/SO(4) \) has widely adopted the basis introduced in [9], given by:

\[
(T^a_{L,R})_{ij} = -\frac{i}{2} \left[ \epsilon^{abc} \left( \delta^a_i \delta^b_j - \delta^a_j \delta^b_i \right) \pm \left( \delta^a_i \delta^b_j - \delta^a_j \delta^b_i \right) \right] ,

T^a_{ij} = -\frac{i}{\sqrt{2}} \left( \delta^a_i \delta^b_j - \delta^a_j \delta^b_i \right) .
\]

(B.1)
However, we find it more convenient to use the basis obtained by a similarity transformation defined by the unitary matrix:

\[
P = \frac{1}{\sqrt{2}} \begin{pmatrix}
0 & 0 & i & 1 & 0 \\
i & -1 & 0 & 0 & 0 \\
i & 1 & 0 & 0 & 0 \\
0 & 0 & -i & 1 & 0 \\
0 & 0 & 0 & 0 & \sqrt{2}
\end{pmatrix}.
\] (B.2)

Explicitly we have:

\[
T^1_L = \begin{pmatrix}
0 & 0 & 0 & 0 & 0 \\
\frac{1}{2} & 0 & 0 & 0 & 0 \\
0 & 0 & \frac{1}{2} & 0 & 0 \\
0 & \frac{1}{2} & 0 & 0 & 0 \\
0 & 0 & 0 & 0 & 0
\end{pmatrix},
T^2_L = \begin{pmatrix}
0 & -\frac{i}{2} & 0 & 0 & 0 \\
\frac{i}{2} & 0 & 0 & 0 & 0 \\
0 & 0 & 0 & -\frac{i}{2} & 0 \\
0 & 0 & \frac{i}{2} & 0 & 0 \\
0 & 0 & 0 & 0 & 0
\end{pmatrix},
T^3_L = \begin{pmatrix}
\frac{1}{2} & 0 & 0 & 0 & 0 \\
0 & -\frac{1}{2} & 0 & 0 & 0 \\
0 & 0 & 1 & 0 & 0 \\
0 & 0 & 0 & -\frac{1}{2} & 0 \\
0 & 0 & 0 & 0 & 0
\end{pmatrix},
\]

\[
T^1_R = -\begin{pmatrix}
0 & 0 & \frac{1}{2} & 0 & 0 \\
\frac{1}{2} & 0 & 0 & 0 & 0 \\
0 & \frac{1}{2} & 0 & 0 & 0 \\
0 & 0 & 0 & 0 & 0
\end{pmatrix},
T^2_R = \begin{pmatrix}
0 & 0 & -\frac{i}{2} & 0 & 0 \\
\frac{i}{2} & 0 & 0 & 0 & 0 \\
0 & 0 & 0 & -\frac{i}{2} & 0 \\
0 & 0 & \frac{i}{2} & 0 & 0 \\
0 & 0 & 0 & 0 & 0
\end{pmatrix},
T^3_R = \begin{pmatrix}
-\frac{1}{2} & 0 & 0 & 0 & 0 \\
0 & -\frac{1}{2} & 0 & 0 & 0 \\
0 & 0 & 1 & 0 & 0 \\
0 & 0 & 0 & 1 & 0 \\
0 & 0 & 0 & 0 & 0
\end{pmatrix},
\]

\[
T^1 = \begin{pmatrix}
0 & 0 & 0 & 0 & 0 \\
0 & 0 & 0 & \frac{1}{2} & 0 \\
0 & 0 & 0 & 0 & 0 \\
0 & \frac{1}{2} & 0 & 0 & 0 \\
0 & \frac{1}{2} & 0 & 0 & 0
\end{pmatrix},
T^2 = \begin{pmatrix}
0 & 0 & 0 & 0 & 0 \\
0 & 0 & 0 & 0 & \frac{i}{2} \\
0 & 0 & 0 & 0 & 0 \\
0 & 0 & \frac{i}{2} & 0 & 0 \\
0 & 0 & \frac{i}{2} & 0 & 0
\end{pmatrix},
\]

\[
T^3 = \begin{pmatrix}
0 & 0 & 0 & 0 & 0 \\
0 & 0 & 0 & 0 & 0 \\
0 & 0 & 0 & 0 & 0 \\
0 & \frac{1}{2} & 0 & -\frac{1}{2} & 0 \\
\frac{1}{2} & 0 & 0 & -\frac{1}{2} & 0
\end{pmatrix},
T^4 = \begin{pmatrix}
0 & 0 & 0 & 0 & -\frac{1}{2} \\
0 & 0 & 0 & 0 & 0 \\
0 & 0 & 0 & 0 & 0 \\
0 & 0 & \frac{i}{2} & 0 & \frac{i}{2} \\
0 & \frac{i}{2} & 0 & \frac{i}{2} & 0
\end{pmatrix}.
\] (B.3)

Then, for instance, the fermionic 5_{2/3} containing the LH top and bottom reads:

\[
\frac{1}{\sqrt{2}} \begin{pmatrix}
-i(b_L + \chi_L) \\
-b_L + \chi_L \\
-i(t_L - t'_L) \\
t_L + t'_L \\
\sqrt{2}S_L
\end{pmatrix} \rightarrow \begin{pmatrix}
t_L \\
b_L \\
\chi_L \\
t'_L \\
S_L
\end{pmatrix} \Leftrightarrow \begin{pmatrix}
t_L \chi_L \\
b_L \\
t'_L \\
S_L
\end{pmatrix} \oplus S_L,
\] (B.4)
where the first vector is in the basis of Eq. (B.1), the second in our basis, Eqs. (B.3), and the last column makes the connection to the \( SO(4) \simeq SU(2)_L \times SU(2)_R \subset SO(5) \) notation. In the main text, we have used the notation \( Q^L = (t_L, b_L)^T, Q^2_L = (\chi_L, t'_L)^T \).

For the Higgs field, we have:

\[
\begin{pmatrix}
   h_1 \\
   h_2 \\
   h_3 \\
   \hat{f}
\end{pmatrix} \rightarrow \begin{pmatrix} 1 \end{pmatrix} = \begin{pmatrix} \frac{1}{\sqrt{2}} \\
   h_4 + i h_3 \\
   \frac{1}{\sqrt{2}} \hat{f} \\
   h_4 - i h_3
\end{pmatrix} \begin{pmatrix}
   H^0* \\
   -H^- \\
   H^+ \\
   H^0
\end{pmatrix} \iff \begin{pmatrix}
   H^0* \\
   -H^- \\
   H^+ \\
   H^0
\end{pmatrix} \end{eqnarray}
\]

In the main text, we have used the notation \( \tilde{\phi} = (H^0*,-H^-)^T, \phi = (H^+,H^0)^T \).

### C Computation of the pNGB Potential

In this appendix we collect a few details of the computation of the pNGB Higgs effective potential, focusing on the contributions to the coefficients \( \alpha \) and \( \beta \) defined in Eq. (3.1). These are obtained by evaluating the pNGB effective potential in the (unitary gauge) constant backgrounds, \( U_1 = 1 \) and [see Eq (B.3)]

\[
U_5 = e^{\sqrt{2}i \alpha T_1/F} = \begin{pmatrix}
   \cos^2 \left( \frac{h}{2f} \right) & 0 & 0 & \sin^2 \left( \frac{h}{2f} \right) & \frac{\sin \left( \frac{h}{f} \right)}{\sqrt{2}} \\
   0 & 1 & 0 & 0 & 0 \\
   0 & 0 & 1 & 0 & 0 \\
   \sin^2 \left( \frac{h}{2f} \right) & 0 & 0 & \cos^2 \left( \frac{h}{2f} \right) & \frac{\sin \left( \frac{h}{f} \right)}{\sqrt{2}} \\
   -\frac{\sin \left( \frac{h}{f} \right)}{\sqrt{2}} & 0 & 0 & -\frac{\sin \left( \frac{h}{f} \right)}{\sqrt{2}} & \cos \left( \frac{h}{f} \right)
\end{pmatrix},
\]

after expanding for small \( s_h = \sin(h/f) \). We treat separately the contributions from the states of spin-1, 1/2 and 0.

#### C.1 Vector Resonances

As is commonly done in CH models, we integrate over the vector resonances. The elementary gauge fields will pick up form factors. In momentum space, the relevant spin-1 Lagrangian reads (see, for instance, [52])

\[
\mathcal{L}_G = \frac{P_{\mu \nu}}{2} \left( \Pi_W W^a_\mu W^a_\nu + \Pi_B B_\mu B_\nu + \Pi_1 \frac{s_h^2}{4} [W^{a}_\mu W^a_\nu + B_\mu B_\nu - B_\mu W^{3}_\nu - W^{3}_\nu B_\mu] \right),
\]

with \( P_{\mu \nu} = \eta_{\mu \nu} - p_\mu p_\nu / p^2 \) and

\[
\Pi_W(p^2) = \frac{-p^2 + \frac{m^2}{g_0^2} + \frac{m^2}{g_\rho^2} + \frac{m^2}{g_X^2}}{g_0^2 p^2 - m^2}, \quad \Pi_B(p^2) = -\frac{p^2}{g_0^2} + \frac{p^2}{g^2_\rho} + \frac{m^2}{g^2_X} + \frac{m^2}{g^2_X},
\]

\[
\Pi_1(p^2) = f^2 + p^2 \left[ \frac{f^2}{p^2 - m^2_x} - \frac{f^2}{p^2 - m^2_\rho} \right] = \frac{f^2 m^2 x^2}{(p^2 - m^2_\rho)(p^2 - m^2_x)},
\]
where Eq. (2.41) has been used. The NGB potential can then be written as

\[ V_V = \frac{3}{32\pi^2} \int dp^2 p^2 \left[ 2 \log \left( 1 + \frac{s_h^2}{4} \frac{\Pi_1(-p^2)}{\Pi_W(-p^2)} \right) + \log \left( 1 + \frac{s_h^2}{4} \left[ \frac{\Pi_1(-p^2)}{\Pi_W(-p^2)} + \frac{\Pi(-p^2)}{\Pi_B(-p^2)} \right] \right) \]

(C.4)

corresponding to the contributions of the W and Z bosons respectively. It is manifestly UV finite.

In the parametrization of Eq. (3.1) one has

\[ \alpha_1 = -\frac{3}{64\pi^2} f^2 m_p^2 \left( 3g_2^2 + g_1^2 \right) \frac{\log r_v}{r_v - 1}, \]

\[ \beta_1 = -\frac{3f^4}{16(4\pi)^2} \left( 2g_4^4 \log \frac{m_p^2}{m_W^2(h)} + (g_2^2 + g_1^2)^2 \log \frac{m_p^2}{m_W^2(h)} \right. \]

\[ + \left[ 2g_4^4 + (g_2^2 + g_1^2)^2 \right] \left( \frac{3 - r_v}{r_v} \log r_v - \frac{r_v^2 + 1}{r_v - 1} \right) \]

(C.5)

where we have approximated \( g_4^2, g_X^2 \gg g_0^2, g_0^2 \), i.e. \( g^2 \approx g_0^2 \) and \( g^2 \approx g_0^2 \) and \( r_v = m_p^2/m_4^2 < 1 \). Note that the \( U(1)_X \) sector does not enter at leading order in these expansions.

### C.2 Fermion Resonances

The fermion mass matrix is most easily evaluated in the unrotated (non-HLS) basis, where

\[ \tilde{\phi} = \frac{1}{\sqrt{2}} \begin{pmatrix} s_h \\ 0 \end{pmatrix} \hat{f}, \quad \phi = \frac{1}{\sqrt{2}} \begin{pmatrix} 0 \\ s_h \end{pmatrix} \hat{f}, \quad \phi_5 = c_h \hat{f}. \]

(C.6)

Substituting these fields, the mass terms are given as

\[ \mathcal{L}_{-1/3} = -\mu_{QQ} \bar{Q}_{L}^{1,2} Q_{R}^{1,2} + \text{h.c.}, \quad \mathcal{L}_{5/3} = -\mu'_{QQ} \bar{Q}_{L}^{2,1} Q_{R}^{2,1} + \text{h.c.}, \]

(C.7)

where \( Q_{L}^{1,2} \) and \( Q_{R}^{1,2} \) are the charge \(-1/3\) components of \( Q_{L}^{1} \) and \( Q_{R}^{1} \), respectively, while \( Q_{L}^{2,1} \) and \( Q_{R}^{2,1} \) are the charge \(+5/3\) components of \( Q_{L}^{2} \) and \( Q_{R}^{2} \), respectively. In the charge \( 2/3 \) sector, we have

\[ \mathcal{L}_{2/3} = -\left( \bar{S}_{L} \tilde{Q}_{L}^{2,2} \bar{Q}_{L}^{1,1} \tilde{q}_{L} \right) \begin{pmatrix} \xi f c_h & 0 & \mu_{IS} & 0 \\ \xi f^2 c_h & \mu'_{QQ} & 0 & 0 \\ \xi f s_h & 0 & 0 & \mu_{QQ} \\ 0 & 0 & 0 & \mu'_{Q} \end{pmatrix} \begin{pmatrix} S_{R} \\ \bar{Q}_{R}^{2,2} \\ t_{R}^{1,1} \\ \bar{Q}_{R} \end{pmatrix} + \text{h.c.}, \]

(C.8)

where \( Q_{L}^{1,1}, Q_{R}^{1,1}, Q_{L}^{2,2} \) and \( Q_{R}^{2,2} \) are the charge \( 2/3 \) components of \( Q_{L}^{1}, Q_{R}^{1}, Q_{L}^{2} \) and \( Q_{R}^{2} \), respectively. All phases can be reabsorbed into the different fields, so we take all parameters
real and positive. Only the charge $\frac{2}{3}$ fermions contribute to the effective potential. One can evaluate the characteristic polynomial of the matrix $\mathcal{M}_F$ appearing in $\mathcal{L}_{2/3}$

$$\chi(p^2) \equiv \det(\mathcal{M}_F^2\mathcal{M}_F - p^2) = \chi_0(p^2) + s_h \chi_1(p^2) ,$$

with

$$\chi_0 = p^2(p^2 - \xi^2 \hat{f}^2 - \mu_{iS}^2)(p^2 - \mu_{QQ}^2)(p^2 - \mu_{\tilde{q}Q}^2 - \mu_{\tilde{q}Q}^2)$$

$$\chi_1 = \frac{\xi^2 \hat{f}^2}{2} \left( p^4[2\mu_{iS}^2 - \mu_{\tilde{q}Q}^2 - \mu_{\tilde{q}Q}^2] ight.$$  

$$+ p^2[(2\mu_{\tilde{q}Q}^2 + \mu_{\tilde{q}Q}^2)\mu_{\tilde{q}Q}^2 - (\mu_{\tilde{q}Q}^2 + 2\mu_{\tilde{q}Q}^2 + \mu_{\tilde{q}Q}^2)\mu_{iS}^2] + \mu_{iS}^2\mu_{\tilde{q}Q}^2\mu_{\tilde{q}Q}^2) .$$

The first term corresponds to the unperturbed mass eigenvalues, the second term encodes the effects of EWSB. Notice that Eq. (C.9) is exact as $\chi(p^2)$ does not have terms beyond quadratic order in $s_h$.

In terms of $\chi$ it is easy to write down the fermion contribution to the effective potential

$$V_F = -\frac{N_c}{8\pi^2} \int dp^2 p^2 \log \chi(-p^2) .$$

One obtains

$$\alpha_{1/2} = \frac{3}{4\pi^2} \int dp^2 p^2 \frac{\chi_1(-p^2)\chi_0(-p^2)}{\chi_0(-p^2)} , \quad \beta_{1/2} = \frac{3}{4\pi^2} \int dp^2 p^2 \left( \frac{\chi_1(-p^2)}{\chi_0(-p^2)} \right)^2 ,$$

One notices that $\alpha_{1/2}$ is IR finite but has a logarithmic UV divergence proportional to $\mu_{\text{eff}}^2 = 2\mu_{iS}^2 - \mu_{\tilde{q}Q}^2 - \mu_{\tilde{q}Q}^2$ (in the limit $\mu_{\tilde{q}Q} \to \infty$ the divergence is instead proportional to $\mu_{\text{eff}}^2 = 2\mu_{iS}^2 - \mu_{\tilde{q}Q}^2$), as argued diagrammatically in Section 3. Conversely, $\beta_{1/2}$ is UV finite but logarithmically IR divergent, to be regularized by the top mass.

It is useful to explicitly extract the UV divergent piece from $\alpha_{1/2}$ by writing $\alpha_{1/2} = \alpha_{1/2}^{\text{div}} + \alpha_{1/2}^{\text{fin}}$ with $^{24}$

$$\alpha_{1/2}^{\text{div}} = \frac{3}{4\pi^2} \int dp^2 \frac{\xi^2 \hat{f}^2}{2} \frac{\mu_{\text{eff}}^2}{p^2 + m_{\tilde{H}}^2} , \quad \alpha_{1/2}^{\text{fin}} = \frac{3}{4\pi^2} \int dp^2 \left( p^2 \frac{\chi_1(-p^2)}{\chi_0(-p^2)} - \frac{\xi^2 \hat{f}^2}{2} \frac{\mu_{\text{eff}}^2}{p^2 + m_{\tilde{H}}^2} \right) .$$

In the $\overline{MS}$ scheme one obtains

$$\alpha_{1/2}^{\text{div}} = \frac{3}{8\pi^2} \xi^2 \hat{f}^2 \mu_{\text{eff}}^2 \left( \log \frac{M^2}{m_{\tilde{H}}^2} + 1 \right) ,$$

where $M$ is the RG scale.

While the UV finite integrals in $\alpha_{1/2}^{\text{fin}}$ and $\beta_{1/2}$ can be performed straightforwardly, the expressions are rather cumbersome so we do not report them here.

$^{24}$The choice of the IR scale $m_{\tilde{H}}$ in this decomposition is done for later convenience.
C.3 Scalar Resonance

The scalar sector also contributes to the NGB potential due to the $SO(5)_L$ violating coupling $\delta m^2$ introduced in Section 3. The scalar mass matrix is given by

$$
M^2_S = \begin{pmatrix}
(m^2_4 + \lambda H^2) & 1_{3 \times 3} \\
1_{3 \times 3} & m^2_4 + \lambda (1 + 2 s_h^2) H^2 & 2 \lambda s_h c_h H^2 \\
2 \lambda s_h c_h H^2 & m_1^2 + \lambda (3 - 2 s_h^2) H^2 
\end{pmatrix}.
$$

(C.15)

The vacuum expectation value of the radial field $H$ is given by $\hat{f}^2 = -m_1^2/\lambda$. In this vacuum, one obtains the effective potential

$$
V_S = \frac{1}{32 \pi^2} \int dp^2 p^2 \log \left(\left[(p^2 + \delta m^2 + m^2_h s_h^2)(p^2 + m^2_h c_h^2) - m^4_4 s^2_h c^2_h]\right)
$$

(C.16)

and hence

$$
\alpha_0 = -\delta m^2 \hat{f}^2 + \frac{1}{16 \pi^2} m^2_4 \delta m^2 \left(\log \frac{M^2}{m^2_h} + 1\right),
$$

$$
\beta_0 = \frac{1}{16 \pi^2} (\delta m^2)^2 \left(1 + \log \frac{m^2_h(h)}{m^2_h}\right),
$$

(C.17)

where $m_h$ is the Higgs mass that we used as an IR cutoff here. Notice that $\beta_0$ is of higher order in $\delta m^2$ and we will hence neglect it.

D Expansion in Powers of $s_h$ and Logarithmic Divergences

In this appendix we clarify the issue of (spurious) IR divergences introduced when naively expanding the Coleman-Weinberg potential in powers of $x = s_h^2$. These arise from an unjustified expansion in the low-momentum region of integration, and is connected to states that acquire mass only as a result of $x \neq 0$. We use the spin-1/2 case for illustration, but the same considerations and conclusions hold true in the spin-1 and spin-0 sectors.

The 1-loop effective potential takes the form $V = -\frac{N}{8 \pi^2} V$, where

$$
V = \int_0^\infty d^2 p p^2 \log \left(\left[f(p^2) + g(p^2) x + \frac{1}{2} h(p^2) x^2 + \cdots\right]\right),
$$

(D.1)

and

$$
f(p^2) = p^2 f_0 + \cdots, \quad g(p^2) = g_0 + \cdots, \quad h(p^2) = h_0 + \cdots.
$$

(D.2)

The expansion in small $x$ is then (neglecting a $x$-independent term):

$$
V = x \lim_{x \to 0} \int_0^\infty d^2 p p^2 \frac{g(p^2)}{f(p^2)} + \frac{x^2}{2} \lim_{x \to 0} \int_0^\infty d^2 p p^2 \frac{f h - g^2}{(f + g x)^2} + \cdots.
$$

(D.3)
The first term is IR safe so we can directly take the limit $x \to 0$. In the second term we first make the shift of variables $p'^2 = p^2 + xg_0/f_0'$, and expand the integrand in $x$ to obtain

$$\mathcal{V} = x \int_0^\infty d^2p^2 \frac{g(p^2)}{f(p^2)} + \frac{x^2}{2} \lim_{x \to 0} \int_{m_0^2}^\infty d^2p^2 \left[ \frac{f(p^2)h(p^2) - g^2(p^2)}{f^2(p^2)} + \mathcal{O}\left( \frac{x}{p^2} \right) \right] + \cdots,$$

where $m_0^2 = (g_0/f_0') s_h^2$ is the (field-dependent) “zero-mode” mass squared. The fist term in the brackets gives a contribution from the lower limit of integration of the form $A \log(m_0^2) + B$. The $\mathcal{O}\left( \frac{x}{p^2} \right)$ term in the brackets gives only terms of order $x \log x$ and hence vanishes in this limit. The upshot is that one can obtain the correct small $x$ expansion by naively expanding the integrand, but cutting off the resulting IR divergence at the (field dependent) “zero-mode” mass, $m_0$. In practice, using the top (or $W$ or Higgs) mass at the minimum of the potential, i.e. the physical mass, does not introduce a large difference compared to the more correct field-dependent one (see also [52]).

## E RG Equations in the Presence of QCD Interactions

In this appendix we collect the RG equations used in the generation of Figs. 1 and 3, meant to illustrate the effect of the gauge interactions on the fixed point behavior discussed in the main text:

$$\beta_{\xi^2} = \frac{\xi^2}{16\pi^2} \left\{ (17 + N)\xi^2 - 16g_3^2 \right\},$$

$$\beta_\lambda = \frac{1}{16\pi^2} \left\{ 2(N + 8)\lambda^2 - 24\xi^4 + 24\xi^2\lambda \right\},$$

$$\beta_{\mu_{\text{eff}}^2} = \frac{\mu_{\text{eff}}^2}{16\pi^2} \left\{ \xi^2 - 16g_3^2 \right\},$$

$$\beta_{\delta m^2} = \frac{3\xi^2}{4\pi^2} \mu_{\text{eff}}^2 + \frac{\lambda + 3\xi^2}{4\pi^2} \delta m^2,$$

where $g_3$ is the QCD coupling constant and we have taken $N_c = 3$.

In the main text we also used that

$$\gamma_L = \frac{\xi^2}{32\pi^2}, \quad \gamma_R = \frac{N\xi^2}{32\pi^2}, \quad \gamma_\Phi = \frac{N_c\xi^2}{8\pi^2},$$

where $\gamma_L$ is the anomalous dimension of $F_L$ and $\gamma_R$ that of $S_R$. Using the Landau gauge ($\xi = 0$) for QCD, there are no 1-loop contributions to the fermion anomalous dimensions from $g_3$.
