Introduction

A congenital lacrimal fistula is a rare developmental anomaly of the lacrimal system typically located in the inferomedial aspect of the medial canthus. The fistulae can originate from common canaliculus, lacrimal sac or nasolacrimal duct of skin. In 1675, the first description of congenital lacrimal sac was reported by Rasor. This paper is to report on atypical case of unilateral congenital double lacrimal sac fistula.

Case report

A 10 year-old girl presented to our clinic with chief complaint of epiphora from right eye and for her evaluation of two small holes present inferonasal to the medial canthus since birth. On physical examination two small holes were present near the nose below the medial canthal of right eye that were associated with congenital double lacrimal sac fistula. Lacrimal sac regurgitation test was positive on both fistulas. Evaluation of the lacrimal system was performed under general anesthesia. Both fistulae were connected to the sac lacrimal by probing the orifice of the fistulae and finding that probe ran in the direction of the sac lacrimal, and she was treated successfully by primary fistulectomy. The postoperative course was free of symptom at 4 years follow-up. In review of the literature, only 1 case of congenital double lacrimal fistula has been previously reported.

Abstract

A 10 years old girl presents to our eye clinic with a chief complaint of watering from right eye and for the evaluation of two small holes present inferonasal to the medial canthus since birth. On physical examination two small holes were present near the nose below the medial canthal of right eye that were associated with congenital double lacrimal sac fistula. Lacrimal sac regurgitation test was positive on both fistulas. Evaluation of the lacrimal system was performed under general anesthesia. Both fistulae were connected to the sac lacrimal by probing the orifice of the fistulae and finding that probe ran in the direction of the sac lacrimal, and she was treated successfully by primary fistulectomy. The postoperative course was free of symptom at 4 years follow-up. In review of the literature, only 1 case of congenital double lacrimal fistula has been previously reported.

Keywords: lacrimal fistula, lacrimal sac, congenital fistula, fistulectomy

Under general anesthesia, standard surgical preparation were carried out, Lidocaine 2% with adrenaline was infiltrated as required along the incision for the purpose of haemostasis. The lacrimal fistula was probed with a No 0 Bowman lacrimal probe to the lacrimal sac. A second probe was inserted into lower canaliculus and sac lacrimal (Figure 2). Fine subcutaneous dissection under microscope is performed. A skin fusiform incision was made around conservatively the orifice of the fistula. Both the tracts were dissected completely down to their junction the lacrimal sac with Westcott scissors. The probe was removed and the remnant tract was ligated with 6/0 polyglactin 910 suture and no regurgitation of fluid was noted on syringing. The fistulous tract was then cut above the tie, and the subcutaneous tissue and skin was closed in layers (Figure 3). At follow-up after four years, the patient was asymptomatic.

Figure 2 The lacrimal probes that has been inserted in fistulas in the direction of the lacrimal sac.

Figure 3 The fistulous tract has been dissected out and base of tract is tied.
Discussion

Congenital lacrimal fistula are uncommon developmental anomalies of the nasolacrimal excretory system with an estimated incidence of one in 2000 births\(^2,3,9,11\) and occasionally can be inherited in an autosomal dominant\(^4,7,11\) or recessive pattern.\(^1,3,4,13\) They are usually unilateral\(^2,3,5,12\) but familial cases are associated with higher incidence of bilaterality.\(^4,9\) There does not appear to be a sex or race predilection.\(^2,8,11,12\) In most of the cases they are asymptomatic\(^3,4,11\) however in some cases it may present with epiphora or discharge\(^2,9\) or mucoid secretion may be expressed by placing pressure on the sac, causing reflux.\(^7,12\) The nasolacrimal system is usually patent.\(^3,6\) The clinical presentation may delay for many years after birth due to evaporation of small amounts of discharge.\(^2\) In this case, the patient had history of epiphora since birth and had no associated infectious complication. A review of the literature, only 1 case of congenital double lacrimal fistula has been previously reported with both fistulae connected to the common canaliculus.\(^9\) In our case, the fistulae were connected to the lacrimal sac.

During the sixth week of embryological development, neuroectodermal cells which are in the naso-optic groove between the lateral nasal and maxillary processes form a solid epithelial cord. After canalization the upper portion of the cord forms the canaliculus and the lower part forms the nasolacrimal canal. In the middle part forming the lacrimal sac, the epithelial cords are thicker, and therefore when the sac canalizes it has a larger diameter than the canaliculus or the nasolacrimal duct.\(^1\) An incomplete separation of the cord from the surface epithelium or an abnormal out-budding of the buried ectodermal cord can result in supernumerary puncta or canaliculus.\(^2,4,9\)

The pathogenesis of lacrimal sac fistula is uncertain.\(^2,3,8,10,12\) Some authors suggest the following explanation: a failure of the surface ectoderm to fuse after invagination of the epithelial cord;\(^2\) an overdevelopment or out budding of the lacrimal duct ; an abnormality of amniotic bands ; a primary developmental arrest with secondary inflammation, an incomplete closure of the embryonic facial fissure;\(^3,4,12\) that the lacrimal fistula is really an extra canaliculus extending from the common canaliculus to the skin in the medial canthal area while the superior and inferior canaliculi are also being formed and that a defect interfering with the invagination, burial, and later tissue remodeling of the surface ectoderm was responsible.\(^12\) Most of these fistulae originate in the common canaliculus, in other cases they may arise from the lacrimal sac or nasolacrimal duct\(^6\) They can be seen externally as small orifices or pits characteristically located inferior and or medial to the medial canthus how to the present case.

Congenital lacrimal fistula can be associated with ocular pathologies including dacryocystitis, agenesis of the lacrimal punctum and canaliculus, lacrimal tract stenosis, strabismus, hypertelorism,\(^3,9\) double lower lid puncta, canalicular atresia , orbital meningocele, mucocele and nasolacrimal duct stenosis.\(^5\) Systemic associations with lacrimal fistula are so rare it requires genetic testing. Associated systemic disorders including CHARGE syndrome (coloboma, heart anomalies, choanal atresia, retardation of growth and development, genital and ear anomalies), Waardenburg-Klein syndrome, ectrodactyly-ectodermal-dysplasia-clefting syndrome,\(^4\) VACTERL syndrome (vertebral anomalies, anal atresia, cardiac malformations, trachea-esophageal fistula, renal and limb anomalies), preauricular fistulae, hypospadias, thalassemia and Down syndrome,\(^1,4,8,10\) uterus didelphys, renal agenesis ectopic pelvic kidney\(^9\) have been reported.

The treatment of choice for a symptomatic fistula is surgery,\(^7,9,11\) these options includes complete excision of the fistulous tract, excision with intubation\(^1,3,9,10\) or dacryocystorhinostomy.\(^2,4,8,10\) In the case of lacrimal fistula without symptoms the observation is the best choice.\(^4,6\) In this case, the girl had only lacrimation during the lacrimal fistulas, and there was no combined nasolacrimal duct obstruction. Fistulectomy alone caused the girl to be free of symptoms at 4 years post operatively a surgical procedure on a congenital lacrimal sac fistula, it is necessary to demonstrate adequate drainage from the nasolacrimal apparatus through a patent nasolacrimal duct. This can be done by dye disappearance and irrigation testing.
