Abstract
Objectives
This study evaluated whether parent-child attachment and self-esteem may mediate the relationship between parental marital conflict and increases in features of internet gaming disorder (IGD) in children at one year.

Method
The baseline and one-year follow-up data for 268 children from the iCURE study were collected. The students were “non-cases of high risk of IGD” in the initial self-reported assessment, anyone living with both parents, current game user at baseline, and those who completed a 12-month follow-up assessment. The Internet Game Use-Elicited Symptom Screen (IGUESS) was used to identify increases in IGD features at 12 months. To examine a potential mediation effect, structural equation modeling was performed.

Results
The direct effect was statistically significant, and parental marital conflict at baseline significantly predicted the increases in IGD features in children at the 12-month follow-up after adjusting for gender, sex, socioeconomic status, and baseline IGUESS score (β=0.206, P=0.003). The indirect effect showed that attachment to fathers through self-esteem was a significant mediating effect (β=0.078, P=0.045). Parental marital conflicts were associated with increases in IGD features in children through poor father-child attachment, and in turn, the lower levels of self-esteem in the children.

Conclusion
Parents, especially fathers, should make an effort to bond with their children to reduce the risk of their children’s developing the IGD features.

Introduction
Computers, video games, and technological devices are part of most young people’s everyday lives. Prolonged and improper use of the internet and related products may result in harmful effects, including internet gaming disorder (IGD). Children may be particularly vulnerable as their abilities and tendencies to self-regulate are not fully developed, and they are prone to spending prolonged periods playing internet games and using the internet for other purposes 1.

The family typically plays an important role in influencing socialization in the early years of life 2. The parents’ marital relationship is usually an important influence on child development 3. Children’s exposure to parental marital conflict may increase risky behavioral and emotional problems 4,5, including internet addiction in adolescents and young adults 6-9. While parental marital conflict is a potential risk factor for IGD in children, little is known about the mechanisms underlying the relationship between parental conflict and IGD propensity.

Frequent exposure to high levels of marital conflict may result in poor parent-child attachment 10. Robust relationships between parents and their children typically promote maturation into emotionally stable, well-adjusted adults, whereas poor attachment relationships may lead to insecurity, anger, and acting-out among children 11,12. Thus, parents may contribute importantly to supporting and protecting their child’s psychosocial development by promoting self-esteem through close and warm relationships during childhood 13. Childhood is a critical period for establishing self-esteem and lower levels of self-esteem have been associated with risky behaviors, such as substance use and delinquency 14-16.

Historically, studies grounded in the attachment theory have focused primarily on the
mother-infant relationship, while attachment to the father has been shown to be positively related with higher levels of self-esteem in school-aged children. A previous study reported that roles of father and mother differentially effected on adolescents' problematic internet use.

The theoretical framework of the study is based on the attachment theory. According to the attachment theory, family harmony and openness were linked with secure attachment. The relationships with parents impact the formation of an internal working model of attachment. Internal working models are generally conceptualized as beliefs on the self and others. Poorer and conflicting family relationship can be affected development of IGD. Game players have been found to depend on gaming to gain self-esteem, to compensate for weak self-image by exhibiting mastery, escaping reality or overcoming difficulties in social interaction. A hypothetical model is presented in Figure 1.

To the best of our knowledge, no study has investigated the mechanisms connecting parental marital conflict with increases in IGD features over time among pre-adolescent children. We examined whether parent-child attachment via self-esteem at baseline might mediate the relationship between parental marital conflict and increases in IGD features in children from baseline to a 12-month follow-up visit.

Method

Participants

This study was conducted using a subsample of the Internet User Cohort for Unbiased Recognition of Gaming Disorder in Early Adolescence (iCURE) study, which is an ongoing prospective cohort study in Korea. The 3rd, 4th, and 7th grade students participated in the iCURE study. The protocol for the iCURE study was published previously.
hundred-and-ninety-nine children participated in the iCURE study from an eligible population of 1,061 students at six elementary schools in the cities of Seoul and Uijungbu. To examine possible mediating effects of parent-child attachment through self-esteem in the relationship between parental marital conflict and increases in IGD features in children, we included students who met the following criteria: anyone classified as a “non-case of high risk of IGD” in the initial assessment, anyone living with both parents, and current game use at baseline. A “non-case of high risk of IGD” was defined as a student with a total score of < 10 in the Internet Game Use-Elicited Symptom Screen (IGUESS) survey. A current game user was defined as having played games over the past year. Of 399 participants, 294 children met the inclusion criteria. To investigate the effect of parental marital conflict on increases in IGD features at 12 months, we excluded 26 participants who did not complete a 12-month follow-up assessment, leaving 268 children in the final analysis.

Informed consents were acquired from all participants and from one of their parents after explaining the principles of the present research, confidentiality, and the freedom of choice to participate. This study received approval from the Institutional Review Board of The Catholic University of Korea for data analysis (MC19ENSI0001). The iCURE data management board released de-identified iCURE data.

**Measurements**

*Data collection*

Data collection was conducted at the above-mentioned schools during school hours. In the baseline assessment, third-grade and fourth-grade students completed the questionnaires in a class setting; a research assistant read the questions with a standard script to help with comprehension and minimize time demands. In the 12-month follow-up assessments,
all students completed the questionnaires on their own, using a web-based self-administration method, with a supervising research assistant available to answer questions. Average times spent playing internet games during weekdays and weekends (days and minutes) were obtained from the iCURE study baseline data. One of each child’s parents completed a demographic questionnaire at the participant’s home or at a private space at the school, according to the participant’s preference. The parental questionnaire was administered by trained interviewers at the baseline interview in which, the parents’ year of education, employment status, and socioeconomic status (SES) data were obtained.

**Parental marital conflict**

Parental marital conflict was measured using the Children’s Perception of Intraparental Conflict Scale (CPIC), which was developed by Grych, Seid and Fincham (1992) at baseline. Although the full version of the CPIC consists of 49 questions, we only adopted the characters of conflict subscale, which contained 19 items and included four dimensions: conflict frequency (four questions), conflict intensity (five questions), (lack of) conflict resolution (seven questions), and stability of conflict (three questions) to measure children’s perception of their parents’ marital conflicts by conducting a confirmatory factor analysis. The response format was a five-point Likert scale ranging from 1 (never) to 5 (always). Total scores ranged from 19 to 95. Cronbach’s alpha is 0.90 for this subscale.

**Parent-child attachment**

Parent-child attachment was measured using the Inventory of Parent and Peer Attachment-Revised version (IPPA-R) at baseline. The original questionnaire was developed to assess children’s perceptions of the positive and negative affective/cognitive
dimensions of their relationship with their parents, and the questionnaire aimed to be a strong measure of psychological security. The IPPA-R is a 25-item questionnaire with responses on a five-point scale, ranging from 1 (“almost never or never true”) to 5 (“almost always or always true”), with higher scores indicating stronger attachment. Children reported on father-child attachment (25 questions) and mother-child attachment (25 questions) separately. The Cronbach’s alphas of the IPPA-R in the original version were 0.87 in mothers and 0.89 in fathers, and in the present study they were 0.93 and 0.93, respectively.

Self-esteem

Rosenberg’s self-esteem scale has 10 items, each rated on a five-point Likert scale, ranging from 1 (strongly disagree) to 5 (strongly agree) \(^{25}\), with a total score range of 10 to 50. Rosenberg defined self-esteem as an individual’s sense of worthiness, which integrates self-respect and self-confidence. This measure detects feelings of self-acceptance, self-respect, and generally positive self-evaluation. Higher scores indicate greater feelings of self-acceptance, self-respect, and generally positive self-evaluation. Cronbach’s alpha was 0.85 in this study. Self-esteem was evaluated at baseline.

High risk of internet gaming disorder

Self-reported IGD features were assessed by the IGUESS at both baseline and 12-month follow-up. This instrument was created based on the nine IGD criteria established by Diagnostic and Statistical Manual of Mental Disorders (DSM–5). Students were instructed to respond reflecting their gaming behavior within the last 12 months, with each item rated on a four-point scale: 1 = strongly disagree, 2 = somewhat disagree, 3 = somewhat agree, 4 = strongly agree). A higher score indicates greater IGD severity \(^{26}\). A Cronbach’s alpha of 0.80 was observed in this study.
Covariates

Possible confounding factors, including gender, age, family SES, and baseline IGUESS score, were obtained from the iCURE baseline data to control for these variables in the final model. The SES data were obtained from parents’ self-evaluations using a seven-point visual analog scale from very low (1) to extremely high (7). SES was reclassified into the lower level of SES (from 1 to 3) and the higher level of SES (from 4 to 7).

Statistical analysis

Descriptive and correlation analyses were performed using SAS 9.4 (SAS Institute Inc., Cary, NC, USA). Descriptive data were summarized with numbers and percentages for the categorical variables or mean ± SD and ranges for the continuous variables. Structural equation modeling (SEM) was conducted to examine the measurement and mediation models using the Analysis of Moment Structures, version 23.0. (IBM Inc., Chicago, IL, USA). In a confirmatory factor analysis, convergent and discriminant validity examine the extent to which measures of a latent variable share their variance and how they are different from others, respectively. The criterion of Fornell–Larcker (1981) is commonly used to assess the degree of shared variance between the latent variables of the model. According to this criterion, convergent validity is assessed by means of: (1) factor loadings (standardized regression weights), (2) reliability (Cronbach’s alpha), and (3) average variance extracted (AVE). The last entity measures the level of variance captured by a construct versus the variance due to measurement error. Values above 0.7 are considered very good and those between 0.7 and 0.5 is acceptable. Construct reliability (CR) measures whether a set of indicators representing a construct are consistent in their measurement, and it is customary to use the Cronbach’s alpha — values above 0.7.
demonstrate that a scale is internally consistent — for this purpose. In addition, we resolved to estimate the CR, which is a less biased estimate of reliability with an acceptable value of 0.7 and above. According to the Fornell-Larcker testing system, discriminant validity can be assessed by comparing the amount of the variance capture by the AVE construct and the shared variance with other constructs (standard error). The levels of the AVE for each construct should be greater than the squared correlation involving the constructs.

A bootstrapping procedure was used to test and verify the paths and indirect effects for statistical significance with bias-corrected methods. A model fit was assessed using the multiple fit indices in terms of absolute fit, incremental fit, and parsimony fit indices. The absolute fit indices included a chi-square ratio over the degrees of freedom ($\chi^2/df$), the goodness-of-fit index (GFI), and the root mean square error of approximation (RMSEA). The incremental fit indices were assessed using the Tucker-Lewis Index (TLI), the normed fit index (NFI), and the comparative fit index (CFI). The adjusted goodness-of-fit index (AGFI) was used for parsimony fit indices. SEM literature suggests that a model fit is good when $\chi^2/df \leq 3$; $CFI \geq 0.90$, $TLI \geq 0.90$, $GFI \geq 0.90$, $NFI \geq 0.90$, $RFI \geq 0.90$, $AGFI \geq 0.90$, and $RMSEA \leq 0.06$. If the path was not statistically significant in the full hypothetical model, we deleted the insignificant path in the alternative model. We compared the model fit index of the two models and adopted the final model with paths that fit significantly better than others.

Results

Study population

Of the 268 children, 125 (46.6%) were girls. Among the parents, 180 (67.2%) of the
fathers and 177 (60.1%) of the mothers had 13 or more years of education. Most fathers
(98.9%) and mothers (59.7%) were employed. For parent-reported family socioeconomic
level, 75.7% of participants reported higher levels of SES. The average time spent on
internet gaming was 39.4 ± 50.7 minutes per day during weekdays and 59.9 ± 74.8
minutes per day during weekend days (Table 1).

Descriptive statistics in the variables included in the SEM
Correlations among indicators ranged from r = 0.27 to 0.63 and all correlation coefficients
were statistically significant (P < 0.001). Parental marital conflict was negatively
correlated with parent-child attachment, suggesting that marital conflict had an adverse
effect on children’s development of attachment to their parents. Both attachment to
father and to mother were positively correlated with self-esteem. IGD features at 12
months were positively correlated with parental marital conflict and negatively correlated
with parent-child attachment and self-esteem. These results suggest that marital conflict
could be a risk factor for IGD features (Table 2).

Confirmatory factor analysis and convergent and discriminant validities
In line with previous conceptualizations of parental marital conflict and attachment
instruments, we modeled a single latent factor of marital conflict with four indicators,
corresponding with the scores on each of the four subscales measuring conflict frequency,
intensity, stability, and lack of resolution. Both father-child attachment and mother-child
attachment included the two subscales of acceptance and compliment. Self-esteem
consisted of positivity and confidence indicators. All measurement models in our sample
data were adequate. The Cronbach’s alphas ranged from 0.71 to 0.94 in the measurement
subscales. All factor loadings were higher than 0.5. According to the Fornell–Larcker
criterion, the convergent validity of our model was satisfactory. All the AVE values were
above 0.7, indicating a very good fit. Both the Cronbach’s alpha coefficients and CR values
were considered acceptable with the values above 0.7 (Table 3).

*Mediating roles of father-child and mother-child attachment and self-esteem on the association between parent marital conflict and risk of IGD*

In the analysis of the full proposed hypothetical model, standardized regression coefficients were not statistically significant in the three paths, including “parental conflict à self-esteem,” “attachment to father à increases in IGD features,” and “attachment to mother à increases in IGD features” (Table 4). We tested the alternative model after dropping the three insignificant paths in the hypothetical model. Table 5 summarizes the results of the model comparisons. The alternate model showed a relatively reasonable goodness-of-model-fit in the entire index ($x^2$/df =1.504, GFI =0.953, RMSEA =0.043, TLI =0.951, NFI =0.925, CFI =0.973, AGFI =0.921). The absolute fit indices, incremental fit indices, and parsimony fit indices were satisfied. These results indicated a significant role of attachment to parents and self-esteem in the mechanism explaining the relationship between parental marital conflict and increases in IGD features in children (Table 5).

*Final structural equation model*

In Figure 2, standardized path coefficients are displayed in the final SEM, which demonstrates adequate goodness-of-fit measures ($x^2$/df =1.504, GFI =0.953, RMSEA =0.043, TLI =0.951, NFI =0.925, CFI =0.973, AGFI =0.921). This model revealed that parental marital conflict was positively associated with increases in IGD features and negatively associated with parent-child attachment. Attachment was positively associated with self-esteem, and self-esteem was negatively associated with increases in IGD features.
Direct effect, indirect effect, and total effect

In the alternate model, the direct effect was statistically significant, and parental marital conflict at baseline significantly predicted the increases in IGD features at 12-month follow-up after adjusting for gender, age, SES, and baseline IGUESS score ($\beta = 0.206$, $P = 0.003$). The indirect effect showed that attachment to father and self-esteem had significant mediating effects ($\beta = 0.078$, $P = 0.045$). However, attachment to mother and self-esteem had not statistically significant mediating effects ($\beta = 0.027$, $P = 0.081$) in children. The effect of parental conflict on increases in IGD features was partially mediated by father-child attachment through self-esteem (Table 6).

Discussion

The present study examined the roles of parents-child attachments and self-esteem in mediation between parental marital conflict and increases in IGD features among children. Our findings show that marital conflict at baseline was positively associated with increases in IGD features in children 12 months later, and this association was partially mediated by father-child attachment and self-esteem. This finding suggests that the child’s attachment to a father may play a more important mediating role than attachment to a mother in the association between marital conflict and increases in IGD features in children.

Our findings show a significant direct effect in the association between parental marital conflict and increases in IGD features in children. Perceived marital conflict by children has been associated with addictive online behavior $^{31,32}$. Thus, children raised in a more conflict-prone family environment may be at higher risk of gaming problems. It is possible that, because children may not perceive parents’ conflicts as manageable events, they may try to escape the stressful situations by spending more time in the virtual
environments of online games. Similar findings have been reported regarding such problematic childhood behaviors as delinquency and substance abuse, problematic alcohol use, and maladjustment.

The current study shows that self-esteem, together with father-child attachment, partially mediates the association of parental marital conflict with increases in IGD features in children. Parental marital conflict may lead to poor father-child attachment, and in turn, poor father-child attachment may lead to lower levels of self-esteem. Several studies have emphasized the father’s role in the development of healthy emotional functioning in children. Attachment to fathers has been positively related to higher levels of self-esteem. Furthermore, children with positively involved fathers show more psychological adjustment, perform better in school, display less antisocial behavior, and have more successful intimate relationships than children with uninvolved fathers, or those with negatively involved fathers. When children have a quality relationship with their fathers, there is an increased likelihood that their adult life will be happy, satisfying, and characterized by lower degrees of psychological distress. In line with Bowlby’s attachment theory of working models, when a child sees the parent as responsive, accepting, available, and independence-encouraging, a secure attachment develops and the children evaluate themselves as worthy. Furthermore, securely attached adolescents show higher levels of self-esteem than insecurely attached ones.

In terms of the indirect effect, a higher level of parental marital conflict could lead to poor attachment to fathers and low self-esteem, with a subsequent impact on increases in IGD features in children. However, mother-child attachment and self-esteem do not appear to mediate the association between parental marital conflict and increases in IGD features. These findings are consistent with the results of previous longitudinal research. The
findings could be interpreted in terms of the Bowlby's attachment theory, in which affective bonds between infant and caregiver, who is typically a mother, form during infancy. Considering that the participants in our research are elementary school students, it is possible that marital conflict negatively affects the attachment to a father and self-esteem. The relationship with father's had an important role in preventing Internet gaming disorder in adolescents. Perceived father-adolescents relationship was the most protective factor against problematic internet use in Chinese adolescents. Father-child relationship had an indirect effect on the relationship between parental monitoring and Internet gaming disorder, while mother-child relationship did not in Chinese adolescents. A previous study examined the different impacts of mother- and father-child relationships on IGD. Unlike infancy, fatherhood influenced adolescent mental health more than motherhood. Father-child communication style plays an important role in the relationship between adolescent aggressiveness and risk of IGD in Korea. Those finding in line with our results in upbringing of father's role in adolescents’ development.

A previous study reported on the mediating role of parent-child attachment between parental marital conflict and internet addiction in Chinese adolescents. These findings suggested that father-child attachment be as important as mother-child attachment on the development of Internet addiction. Thus, those with attachment problems might spend excessive time on Internet to avoid the emotional distress that results from attachment situations or engage in online rewarding activities to replace adverse relationship experiences.

There were several limitations of this study. First, of the 1,061 eligible students at six elementary schools, only 399 (37.6%) consented to participate in the iCURE study. Therefore, the results may not be reflective of all elementary school students in this
jurisdiction. However, the demographic profile of our sample and daily internet gaming time were similar to those of Korean children based on the nation’s annually reported data. Second, because the information was collected through self-administered questionnaires, we cannot rule out an over- or under-reporting in responding to the gaming-related or other questions. According to a previous finding conducted in a subsample of the iCURE study, the false-negative rate and the false-positive rate for self-reported IGD assessment was 44% and 9%, respectively. Compared to the self-administered method, there is a possibility of underestimation in the evaluation of IGD when the research assistant reads the questionnaire and answers it. However, the size of the underestimation would not have been large because the participants were third or fourth graders.

Third, it is possible that the mother-child attachment mediating effect may not be reliable because of the small sample size. However, it seems that the mediating effect of father-child attachment through self-esteem was a more important mechanism than mother-child attachment in the association between parental marital conflict and increases in IGD features. Despite these limitations, there were several strengths of the current study. We used the 12-month follow-up cohort data to examine the directional hypotheses among relationships between parental marital conflict, parent-child attachment, self-esteem and increases in IGD features, using children without IGD and with current internet gaming use at baseline.

Conclusion

Parental marital conflict was associated with increases in IGD features in children in part through the effects of father-child attachment, and in turn, self-esteem. Higher levels of marital conflict may lead to poor attachment with fathers, and this may lead to lower
levels of child self-esteem, which may influence children’s problematic gaming behaviors. Our findings show that father-child attachment contributes importantly to self-esteem in children and that both father-child attachment and self-esteem may be important factors in controlling the incidence of IGD features. In the public health perspectives, the current findings suggest that parents should avoid conflicts in front of their children to prevent the children from having IGD. Also, health behavior interventions might benefit from a particular focus on both individuals’ styles of attachment to father with the hope of increasing more secure attachments and increased availability of self-esteem for children under parents’ marital conflicts.

Declarations

**Ethics approval and consent to participate**

Written consents were acquired from all participants following explanation of the nature of the principles of research, including confidentiality and the freedom of choice to participate. This study received a full review and an approval from the Institutional Review Board of The Catholic University of Korea (MC19ENSI0001). All procedures were in accordance with the Helsinki Declaration of 1975, as revised in 2013.

**Consent for publication**

Not applicable.

**Data Availability**

The datasets generated during and/or analyzed during the current study are available from the corresponding author.

**Conflict of interest**

The authors declare no conflicts of interest with respect to the content of the manuscript. Dr. Potenza reports the following disclosures. Dr. Potenza has consulted for and advised RiverMend Health, Lakelight Therapeutics/Opiant and Jazz Pharmaceuticals; has received
research support from the Mohegan Sun Casino and the National Center for Responsible Gaming; has participated in surveys, mailings or telephone consultations related to drug addiction, impulse control disorders or other health topics; and has consulted for law offices and gambling entities on issues related to impulse control or addictive disorders.

**Funding**

This study was supported by a grant from the Korean Mental Health Technology R&D Project, Ministry of Health and Welfare, Republic of Korea (HL19C0028).

**Authors' contribution**

HJ conducted the analyses and led the writing of the manuscript. HWY guided and supervised the writing of the manuscript. HJ and HWY developed and proposed the basic idea of the study. SL, HL, and MNP reviewed scientific content and edited the manuscript. HWY, HJ, SJ, and HS contributed to conducting the study. All authors contributed editorial comments on the manuscript.

Tables
Table 1. Children and parents information of 268 participants.

| Variables                                      | n (%) or mean ± SD |
|------------------------------------------------|--------------------|
| Age (years)                                    | 9.4 ± 0.6          |
| Gender                                         |                    |
| Male                                           | 143 (53.4)         |
| Female                                         | 125 (46.6)         |
| Years of father’s education level              |                    |
| 0–12                                           | 88 (32.8)          |
| ≥ 13                                           | 180 (67.2)         |
| Years of mother’s education level              |                    |
| 0–12                                           | 91 (33.9)          |
| ≥ 13                                           | 177 (60.1)         |
| Unemployment                                   |                    |
| Father                                         | 3 (1.1)            |
| Mother                                         | 103 (40.3)         |
| Perceived socioeconomic status                 | 375 (16.2)         |
| Low                                            | 65 (24.3)          |
| Middle to high                                 | 203 (75.7)         |
| Average time spent playing Internet game during weekdays (minutes/day) | 39.4 ± 50.7 |
| Average time spent playing Internet game during weekend (minutes/day) | 59.9 ± 74.8 |

Table 2. Means, standard deviations, and correlation coefficients for variables.

|                     | 1    | 2    | 3    | 4    | 5    | Mean | SD  |
|---------------------|------|------|------|------|------|------|-----|
| 1. Parent marital conflict | 1    |      |      |      |      | 27.6 | 7.9 |
| 2. Attachment to father    |      | 1    |      |      |      | 81.5 | 13.3|
| 3. Attachment to mother   |      |      | 1    |      |      | 96   | 13.1|
| 4. Self-esteem            |      |      |      | 1    |      | 29.9 | 4.8 |
