Systemic sclerosis (SSc) is an autoimmune multisystem disease, characterized by immune activation, autoantibody production, fibroblast dysfunction, extracellular matrix deposition, and vasculopathy (1). Its incidence is about 20 cases/1 million/year, rising in the last years. The SSc prevalence varies from 250 to 350 cases/million people (2, 3).

Major organ involvement (lung, kidney, heart, gastrointestinal tract) is associated with decreased survival in these patients (1). In their study, Steen and Medsger revealed that the 9-year survival in sclerodermic patients with major organs involvement is reduced at 39%, compared with the patients without these comorbidities, in whom the survival is about 72% (4).

Renal involvement represents an important cause of morbidity and mortality in SSc patients. The spectrum of renal complications in SSc includes: scleroderma renal crisis, normotensive scleroderma renal crisis, myeloperoxidase-antineutrophil cytoplasmic antibodies associated glomerulonephritis and vasculitis, penicillamine-associated renal disease, nephropathy induced by antiphospholipid antibodies, isolated urinary abnormalities (proteinuria, microscopic haematuria), isolated reduction in glomerular filtration rate. Another kidney involvement in scleroderma, less studied, is represented by abnormal increase of intrarenal resistance indices, without any clinical or biological signs (5). Evidence of renal disease may identify a subset of patients with scleroderma, who will experience significant morbidity and mortality (6). Subclinical renal impairment affects approximately 50% of scleroderma patients and may be associated with other vascular manifestations. Subclinical renal involvement rarely progresses to end-stage renal failure; however, Shanmu-
gam and Steen suggest that it may predict mortality in patients with other vasculopathic manifestations (5).

Microcirculation of patients with SSc is assessed at the nailfold skin of the fingers of the hands by means of nailfold capillaroscopy. Based on the capillaroscopic abnormalities, Cutolo classified the sclerodermic capillaroscopic pattern into three stages: early (few giant capillaries, few capillary microhaemorrhages, no evident loss of capillaries, and a relatively well-preserved capillary distribution), active (frequent giant capillaries, frequent capillary microhaemorrhages, moderate loss of capillaries, absence of or mildly ramified capillaries with slight disorganisation of the capillary architecture), and late (irregular enlargement of the capillaries, almost absent giant capillaries and microhaemorrhages, severe loss of capillaries with extensive avascular areas, ramified/bushy capillaries, and intense disorganisation of the normal capillary array) (7).

Intrarenal vascularisation may be assessed by means of Doppler ultrasonography of interlobar renal arteries, determining the resistive index (RI) and pulsatile index (PI) (8).

The aim of this study is represented by the assessment of intrarenal vascularization and its correlation with the nailfold capillaroscopy findings in diffuse SSc patients.

MATERIAL AND METHODS

The study was performed on a group of 11 patients with systemic sclerosis without clinical and biological renal abnormalities and 11 sex- and age-matched controls. The diagnosis of SSc was established based on 2013 Classification Criteria for Systemic Sclerosis (9). Exclusion criteria were: isolated urinary abnormalities (microhaematuria and/or proteinuria), primary or secondary kidney diseases (glomerulonephritis, tubular-interstitial nephropathies, nephrolithiasis, renal cysts, vascular nephropathies), arterial hypertension, diabetes mellitus, heart failure, generalized atherosclerosis.

Renal function was assessed by means of glomerular filtration rate (GFR), proteinuria/24 hour, and urinary sediment. GFR was calculated using the formula:

\[
GFR = \frac{\text{urinary creatinine (mg/dl) x urinary volume (ml)}}{\text{serum creatinine (mg/dl) x 1440}}
\]

Serum and urinary creatinine were determined using Jaffe method, proteinuria by biuret method, and urinary sediment by Addis-Hamburger method.

Intrarenal vascularization was characterized by resistive (RI) and pulsatility (PI) indices of interlobar renal arteries. They were determined by means of Doppler ultrasonography, with Siemens Acuson X300 Ultrasound System, with convex 3,5 MHz probe.

Capillaroscopy is a non-invasive imaging technique that is used for in vivo assessment of the microcirculation. In our study, nailfold capillaroscopy was performed with USB Digital Microscope 2.0 mega Pixel Digital Camera.

Before starting this procedure, the patients took place in a room with a stable temperature of 20-22°C for at least 15 minutes, in order to avoid capillaries vasoconstrictions, which can induce false positivity for avascular areas. The 2nd, 3rd, 4th and 5th fingers of both hands were examined. Giant capillaries, capillaries haemorrhages, avascular areas, and capillary architecture were the recorded nailfold capillaroscopic parameters (10,11). Nailfold capillaries density/mm was the parameter used in the statistical analysis.

All the data were presented as mean ± standard deviation. The statistically analysis was done using Pearson’s test and Student’s t-test, p < 0.05 was considered statistically significant.

RESULTS

The group of patients with SSc was formed by 8 females and 3 males, with the mean age of 46.90 ± 4.98 years. All the patients had diffuse form of SSc, with the mean length of evolution of 4.63 ± 2.96 years. Antinuclear antibodies were present in all the patients. The assessed parameters are presented in the Table 1.

| TABLE 1. Clinical and imagistic parameters assessed in sclerodermic patients |
|-----------------------------|-----------------------------|-----------------------------|-----------------------------|
| Parameter | Systemic sclerosis group | Healthy control group | p |
| Age (years) | 46.90 ± 4.98 | 44.9 ± 7.17 | 0.456 |
| Capillaries/mm | 6.25 ± 2.35 | 12.3 ± 1.22 | 0.0000026 |
| Proteinuria (mg/24 hours) | 89.63 ± 14.04 | 94.27 ± 11.26 | 0.441 |
| Urinary sediment (red blood cells/min) | 527 ± 251 | 501 ± 169 | 0.401 |
| GFR (ml/min) | 82.54 ± 6.43 | 101 ± 5.76 | 0.0000072 |
| RI | 0.71 ± 0.03 | 0.62 ± 0.02 | 0.0000079 |
| PI | 1.30 ± 0.08 | 1.13 ± 0.02 | 0.000053 |
In the SSc group, the capillaries density/mm was significantly reduced than in controls (Fig. 1, 2). Our study reveals a strong inverse correlation between the capillaries density and the mean length of disease evolution ($r = -0.85, p < 0.001$) (Fig. 3).

Proteinuria and urinary sediment didn’t show any changes in sclerodermic group. But glomerular filtration rate was significantly reduced in these patients ($p = 0.0000072$). Resistive and pulsatility indices were higher in studied patients than in controls ($p = 0.0000079$ for RI, and $p = 0.000053$ for PI), demonstrating the presence of intrarenal vasoconstriction (Fig. 4). These parameters were correlated with the capillaries density. We found a significant correlation between the capillaries density and GFR ($r = 0.719, p = 0.012$). Other correlations were established between the capillaries density and RI ($r = -0.784, p = 0.004$), respective PI ($r = -0.748, p = 0.008$) (Fig. 5, 6).

**DISCUSSION**

Vascular pathology represents one of the main factors involved in pathogenesis and organ dysfunction in SSc. Vascular involvement in SSc affects predominantly the microcirculation (arterioles and capillaries). Vascular dysfunction and disorganised microvasculature occur early in the disease evolution, and may predict the prognosis (3).

Sclerodermic vessels pathology shows concentric intimal proliferation, marked luminal obstruction, and lymphocyte infiltration (12). Microvasculature changes, such as those assessed by nailfold capillaroscopy, are seen in all involved organs (lungs, heart, kidneys, and gastrointestinal tract), demonstrating the widespread nature of capillary changes in this disease (13).

Renal involvement in SSc could exhibit several forms of different severity, from asymptomatic renal involvement to sclerodermic renal crisis. Trostle et al. reported that the asymptomatic renal pathology was identified from autopsy studies in 60-80% of
sclerodermic patients. They demonstrated that the intimal thickening was present in small and medium-sized arteries of patients with diffuse SSc, but only in small arteries of limited SSc patients, compared with those in controls. The authors concluded that renal vascular structural changes represent an important feature in SSc, with major impact on prognosis (14). Histopathologic renal injury is common
in scleroderma, even without clinically evident sclerodermic renal crisis (5).

In our study, GFR was reduced in scleroderma patients, compared to healthy controls (p < 0.001). However, the lowest value of GFR wasn’t below of 69 ml/min. These values of GFR weren’t accompanied by pathological proteinuria, urinary sediment, or elevated serum creatinine. Kingdon et al. showed that the impairment of renal function can be present in patients with diffuse SSc without clinical and biological sign of renal involvement (15). In another study, Scheja et al. identified that the decreased glomerular filtration rate was found in 11% of limited SSc and 8.6% of diffuse SSc patients (16). In their study, performed on 675 patients with diffuse SSc, Steen et al. reported reduced renal function in 32% of patients. During a period of 10 years, none of the patients developed severe renal failure, suggesting that the asymptomatic reduced of renal function is common in scleroderma, having a benign clinical course (17). It was revealed a correlation between GFR and capillaries density in SSc patients (r = 0.719, p = 0.012). This relation between GFR and capillaries density was described by Rosato et al. in their study (18).

Resistive and pulsatility indices of interlobar renal arteries represent markers of severity renal damage. They evaluate the intrarenal elasticity and compliance. Their elevated value identifies vascular and interstitial nephropathies, because glomeruli are only responsible for 10% of the intraparenchymal flow resistances. Intrarenal vessels remodeling leads to elevation of RI as renal vascular disease progresses (8, 18). In scleroderma patients, renal involvement appearance, even subclinical, is accompanied by the increase of these parameters (18). Our study reveals that these indices were increased in patients with SSc sclerosis, compared to controls (p < 0.001). On the other hand, between these parameters and capillaries density, significant negative correlations were demonstrated (r = -0.784, p = 0.004 for the correlation between capillaries density and RI, respectively r = -0.748, p = 0.008 for the correlation between capillaries density and PI). Rosato et al. showed that the intrarenal indices were significantly increased in sclerodermic patients than in controls. The authors revealed that these indices increased with the progression of capillaroscopic damage progression (18). Rivolta et al. showed that in sclerodermic patients, RI was significantly increased than in controls (19). Aikimbaev et al. demonstrated the increase of Doppler indices of intrarenal vascular resistance in sclerodermic patients, compared with healthy controls, the values of these indices correlating with the disease duration, the age of patients and the plasma renin activity (20). Increased intrarenal resistive index signifies the presence of renal vascular involvement and correlates with GFR and digital microvascular damage in SSc patients (5).

In SSc, some of types of renal involvement do not have an immediate clinical significance. However, in the presence of severe capillaroscopic damage, intrarenal vascularization assessment can show significant vasoconstriction, even in absence of clinical or biological signs of renal involvement (21).

CONCLUSION

In patients with diffuse SSc, assessment of intrarenal vascularization shows a vasoconstrictive pattern. Significant correlations were demonstrated between capillaroscopic findings and the indices which characterizes the intrarenal vascularization and glomerular filtration rate.

In this context, finding severe capillaroscopic damage in a patient with SSc should be followed by the assessment of renal vascular involvement, even in the absence of any clinical or biological signs.
