Abstract

Lectins are ubiquitous in nature and one of the most important secondary metabolites in plants. They are heterogeneous class of proteins that bind specifically and reversibly to carbohydrates and are used as a defence tool against various abiotic and biotic stresses. In this study, we describe generation of transgenic Brassica juncea plants over-expressing chickpea lectin in conferring fungal resistance. In addition, the transgenic plants also showed resistance against salinity (NaCl) and mannitol induced drought stress. The stable integration and transcript expression of the transgene was confirmed by southern blot and RT-PCR analysis in the transgenic plants. The transgenic lines were evaluated for resistance against Alternaria brassicae as assessed by the number and size of lesions and time taken for leaf necrosis, the Alternaria infection was delayed and restricted in the transgenic plants with the protection varying from 36-60% in different transgenic lines compared to the Untransformed Control (UC) plants. In addition, the transgenic Brassica juncea plants also showed tolerance against high salinity and drought stress. The Expression of lectin gene imparts greater water retention capacity, higher proline content and more chlorophyll retention with less membrane damage and reduction in electrolyte leakage in the transgenic plants compared to UC plants. Together, these findings suggest the potential use of chickpea lectin gene to engineer the crop plants for broad spectrum biotic and abiotic stress tolerance to improve crop productivity.

Introduction

Agricultural plants face constant state of war against an array of pathogens and adverse environmental factors which are major causes in limiting crop production and have been responsible for scripting some of the most devastating famines in the human history. Brassica juncea belongs to the Cruciferae family and it is an important oil seed crop grown in many countries around the world. The oil obtained from the seeds is the main cooking medium in different parts of the world, especially in the Indian sub-continent. Brassica is also a high biomass crop and may facilitate phytoremediation of heavy metals in polluted soils [1]. In India, mustard contributes 28.6% to the total oilseed production and has been projected to provide for 41% (14 million tons) of the country’s demand by the year 2020 [2]. Due to increased demand for edible oil and biofuels, the cultivation of oilseeds crops has gained significant importance [3]. Unfortunately, the productivity of this crop has been hampered by several biotic and abiotic factors [4]. Among biotic stress one of the major constraints affecting the productivity of mustard is the Alternaria leaf spot disease caused by Alternaria brassicae [5]. However, the crop is also severely affected by abiotic stresses resulting in significant loss in seed yield. Conventional breeding approaches to develop the resistant cultivars is confounded due to non availability of suitable resistance sources within the available germplasm of cultivated and wild species of Brassica. Therefore, better combat strategies relying on generation of transgenic plants armored with defense proteins are being explored [6].

The plants have inherent defence mechanisms and an innate immune system to protect themselves against a wide range of pathogens by the discrimination between self and non-self through pathogen-associated molecular patterns [7]. The preformed physical and chemical barrier constitutively produced antimicrobial compounds which protects the plants against biotic and abiotic stress. The proteins embedded in the cell wall and plasma membrane is also an important sentinel of the system for the recognition and transduction of defense associated signals [8]. The susceptibility of plants to the pathogens is resulted due to the disruption of cell wall-plasma membrane adhesion during pathogen penetration into host cells, causes reduction in cell wall-associated defense responses, thereby making the plant more susceptible to disease [9].

Lectins are the ubiquitous carbohydrate binding proteins possess at least one non-catalytic domain that specifically and reversibly bind to mono or oligosaccharide structures and mediate different biological processes [10]. Plants lectins is also believed to be tool in the specific protein-carbohydrate interactions within the cytoplasmic and nuclear compartments [11] and to the glycoproteins present on the cell surfaces [12]. Lectin shows high affinity binding with the carbohydrate moiety of glycoproteins, glycolipids, polysaccharides and typical carbohydrate constituent of fungal cell walls [13]. Expression of Gastrodia elata lectins resulted into strong induction of Trichoderma viride, which...
indicates that lectin is an important defence protein in plants [14]. By the incorporation of the precursor gene of stinging nettle isolectin I into tobacco, the spore germination of Botrytis cinerea, Colletotrichum lindemuthianum, and T. viride was significantly reduced [15]. Several other plant lectins are also reported for their crucial role in the defense against phytopathogenic infection such as the potato lectin immobilizes avirulent strains of Pseudomonas solanacearum on the plant cell wall; however, avirulent strain is not recognized by lectins [16]. Herein, a type of lectin produced by rubber tree latex shows in vitro antifungal activity against Botrytis cinerea, Fusarium oxysporum, and Fusarium culmorum [17] and also confers the protection against Alternaria leaf spot in Indian mustard [18]. Different plant lectins show their differential expression under abiotic stress including drought, salinity and temperature shock [18-22] in the different crop plants.

In view of the diversity in the protective action of lectin, we assessed the efficacy of the chickpea lectin gene, which was involved in the suppression of Alternaria leaf spot in Brassica juncea during the fungal infection. Also, the transgenic plants harbouring chickpea lectin showed enhancement in the tolerance to salinity and drought stress in comparison to UC plants. Collectively, the results of our study demonstrated the current efforts to generate broad spectrum of transgenic plants resistance to fungal phytopathogens along with abiotic stresses.

Materials and Methods

Plant material

The seeds of Brassica juncea cv. Varuna were procured from Indian Agricultural Research Institute, New Delhi-12.

Bacterial strain and plasmid

The chickpea lectin cloned at the EcoRI-XbaI site in the pRT101 vector in between CaMV 35S promoter and polyA terminator sequences. This promoter-lectin cDNA-terminator cassette was released from pRT101 vector by digestion with HindIII and cloned at the HindIII site in the multiple cloning site of pCAMBIA 1301 (pCI301) vector to give rise to pCAM-lectin. pCI301 has hygromycin as plant selection maker and kanamycin as bacterial selection marker. This construct was confirmed by restriction digestion with HindIII as well as by PCR amplification of lectin sequence by using specific primers. Further the gene construct was mobilized into Agrobacterium tumefaciens strain GV 3101 by Freeze (Instead of heat) and thaw method. Agrobacterium culture was maintained on solid YEB medium and selected with 50 mg/l kanamycin as bacterial selection marker. This construct was confirmed by digestion with HindIII as well as by PCR amplification of lectin gene) labelled with [α-32P] dCTP using a PCR amplification of lectin gene) labelled with [α-32P] dCTP using Random primer DNA labeling kit (Amersham Biosciences, UK) as per the manufacturer’s instructions) was added to the prehybridization buffer and incubated overnight at 65°C. The membrane was washed (10 min per wash) sequentially in 3X SSC, 0.1% SDS; 0.5X SSC, 0.1% SDS; 0.2X SSC; 0.1% SDS with constant agitation at 65°C. The hybridization signals were captured using phosphorimaging (FLA 5000 imaging system, Fujiflim).

In Vivo plant bioassay for resistance to fungal phytopathogen

The assessment of antifungal activity of lectin tin he UC and TR plants were assessed. Alternaria brassicae (Accession No. ITCC 5097) procured from the Division of Plant Pathology, Indian Agricultural Research Institute, New Delhi. The fungal culture was multiplied on potato dextrose agar (PDA) medium at 22 ± 1°C for the maintenance. The spore suspension was prepared as explained by [24]. The spore suspension was filtered through cheesecloth to remove the mycelia debris. The spores were washed with sterile distilled water and resuspended to a count of 10⁶ spores ml⁻¹. For in vivo plant bioassay, the fourth leaf (from the top) of the 45-day-old UC and TR plants were painted with the spore suspension using a painting brush. The inoculated plants were covered with polybag to maintain the humidity which was conducive to infection. To assess the disease severity the development of necrotic lesions in terms of number and area on the inoculated leaf of UC and TR plants were observed and recorded up to 15 days of inoculation. Percentage disease protection was calculated by [6].

Disease protection (%)={(No: of lesions per leaf in UC plant- No. of lesions per leaf in TR plants)}/(No: of lesions per leaf in UC plant) × 100
Stress tolerance experiments

For drought and salt stress treatments 6-day-old seedlings of UC plantlets grown on MS plates and TR lines grown on MS plates supplemented with 30 mg/l hygromycin were transferred into pots containing agaropeat in a growth chamber at 22 ± 2°C, 60% relative humidity, and 16 h: 8 h (Light:dark) photoperiod. To assess the drought and saline stress the UC and TR plants were irrigated biweekly with 300 mM mannitol and 300 mM NaCl solution respectively followed by rewatered for 6 days to recovery. These plants were used for performing different experiments.

Leaf disc senescence assay

To analyse the preliminary stress responses the leaf disc senescence assay was performed. For leaf disc senescence assay, leaf sections of equal diameter were excised from the fourth leaf from top of UC and TR B. juncea plants and floated on liquid MS basal medium containing NaCl (200–600 mM) or Mannitol (200–600 mM). Chlorophyll content in the leaf sections was estimated after 5 days according to the procedure of [25].

Measurement of electrolyte leakage

The Electrolyte leakage was determined according to the method described by [26]. Leaves from UC and TR plants were harvested and washed with deionized water for three times to remove surfaced electrolytes. Further they were immersed to the 10 ml of deionized water in the test tubes to measure the electrical conductivity (EC1). After incubation for 30 min at 55ºC again EC2 was determined. The Electrolyte leakage was determined according to the method described by [25]. The Electrolyte Leakage was expressed as a percentage of the total conductivity: Relative Electrolyte Leakage = (EC2-EC1)/EC3]×100

Measurement of MDA content

The protocol of Heath and Packer was used to measure MDA content [27]. 1 gm of leaves of UC and TR plants were grinded to fine powder in liquid nitrogen. 3 ml of 10% trichloroacetic acid was added to 0.2 g of the homogenized powder and left at 4ºC for overnight. Further the homogenized powder was centrifuged at 1,000×g for 20 min and supernatant was transferred to a new tube. 2 ml of 0.2% ninhydrin mixture was vortexed thoroughly and heated in boiling water bath for 15 min, cooled immediately and centrifuged. The Absorbance was taken at 532 and 450 nm by using water as blank. The formula for the calculation of MDA content was: MDA content = (μmol/l) = 6.455×OD450/0.56×OD20

Measurement of relative water content (RWC)

To determine the RWC, fresh leaves were detached from the UC and TR plants and weighed their fresh weight followed by dipping them in distilled water for 12 h. The leaves were blotted to wipe off excess water and weighed to record turgid weight (TW). Further leaves were placed at 70ºC for 24 h to record the dry weight (DW). The RWC was determined by the equation:

RWC = (FW - DW)×100/(TW - DW).

Estimation of proline

Proline content was estimated using the standard protocol [28]. 100 mg of leaf tissue from UC and TR plants were homogenized in 10 ml of 3% sulfoalicylic acid. The homogenate was centrifuged at 15,000 rpm. 2 ml of the supernatant was mixed with 2 ml of 0.2% ninhydrin and 2 ml of glacial acetic acid. Further the mixture was incubated at 100ºC for 1 h and the reaction was terminated on ice. Extraction of Proline was done by 4 ml of toluene. The OD of the supernatant was measured at 520 nm and proline concentration was determined from the standard curve made by using the purified L-proline (Sigma, MO, USA) and calculated on a Fresh Weight (FW) basis (μmol/g).

Results

Generation and molecular characterization of transgenic B. juncea expressing chickpea lectin gene

Generation of transgenic B. juncea harbouring chickpea lectin gene was achieved by Agrobacterium mediated genetic transformation. The plasmid, pCAMBIA1301, contains chickpea lectin gene cloned between HindIII restriction site with CaMV 35S constitutive promoter and NOS termination sequence (Figure 1a). The hygromycin phosphotransferase (hpt) gene present in the plasmid was used for putative transformants selection. Preliminary screening for the transgenic B. juncea plants, selected on hygromycin was done by PCR amplification of the chickpea lectin gene. In the six independent transgenic lines, an amplicon of 834 bp was found with the chickpea lectin gene specific primer (Figure 1b). These fragments were not amplified in the UC plants. The six PCR positive TR lines produced southern positive bands with single (L1, L3, L5, L6) and double copy (L2, L4) of the transgene after the restriction digestion with PstI (Figure 1c). To check the expression level of the chickpea lectin gene in the southern positive transgenic lines, RT-PCR analysis was performed followed by the densitometrically normalizing the actin levels. Figure 1d shows the presence of 834 bp band corresponding to the lectin successfully expressed in all the confirmed transgenic lines whereas it was absent in untransformed control plant. All the transgenic plants were morphologically similar to the UC plants and showed no visible signs of impaired growth or physiology. Further these TR lines and the UC plants were used for the

Table 1: Evaluation of Alternaria brassicae infection on B. juncea after 15 days of inoculation. Number of fungal lesions and the diameter range of lesions were determined. The percentage disease protection in the transgenic plants with respect to the Untransformed Control plants was determined as described in materials and methods. The data presented is the average ± SD of three replicate experiments.

abiotic stress tolerance assay and in vivo anti fungal assay against the A. brassicae.

In vivo biotic stress assay

The resistant/tolerant efficiency of the candidate gene against the Alternaria leaf spot disease was determined by in vivo plant bioassay, under controlled environmental condition. In the aforesaid protocol (Material and methods) the leaves of UC and the TR lines were inoculated with fungal spores. Further the initiation and progression of the disease lesions were analyzed in the subsequent days. After 15 days, the number of characteristic lesions on the leaves of transgenic plants was less (<9 lesions/leaf) in comparison to the leaves of the UC plants (>14 lesions/leaf) (Table 1). The size of the lesions ranged between 0.6 to 1.4 cm in diameter in the UC plants as against 0.2 to 1.0 cm in the different TR lines (Table 1). In the UC plants, the concentric rings of lesions were increasing in size until they merged with each other, which resulted into covering of whole lamina by the enlarged necrotic zone and the entire leaf dried up within 30 days of inoculation. The process of the spread of infection took more than 42 days in the case of TR plants. The percentage disease protection in the different TR lines compared with the UC plants varied between 36.6 to 60.6% (Table 1).

Transgenic plants over-expressing lectin showed higher chlorophyll retention, relative water content and proline accumulation with less membrane damage and electrolyte leakage under salt and drought stress

To investigate the effect of salt and drought stress at whole plant level, one month old plants of UC and the TR plants were transferred to the glass house in pots. To assess the effect of lectin expression on the salt and drought tolerance in transformed B. juncea. The one-month-old UC and TR plants were irrigated with 200 mM NaCl solution to induce salt stress and 200 mM of mannitol solution to induce drought stress for 3 weeks and the performance of the UC and TR plants transgenic B. juncea plants were assessed by comparing few parameters that serves as important indicators of abiotic stress tolerance in plants.

Primarily the leaf disc senescence assay was performed to assess the ameliorative effects of lectin over-expression on leaf senescence and loss of chlorophyll due to salinity and drought stress (Figure 2a). There was loss of chlorophyll in UC plants leaf discs due to bleaching as compared to the transgenic plants leaf discs under high salt (200–600 mM NaCl) and Mannitol (200–600 mM) treatments (P ≥ 0.05). Where the UC leaf discs showed 86 and 69% decline in total chlorophyll content due to 600 mM NaCl and 600 mM Mannitol treatments respectively. The% decreases of chlorophyll content in the TR lines L1 and L5 were 57 and 62% due to imposition of salt stress, whereas 34 and 41% reduction in chlorophyll content was observed due to mannitol induced drought stress in the leaf discs excised from the L1 and L5 lines of transgenic plants respectively (Figure 2b).

Relative tolerance of UC and TR plants to the salinity and drought stresses was also assessed by comparing the electrolyte leakage from the leaf tissues of UC and transgenic plants. Under the normal condition the percentage of electrolyte leakage in the UC and TR plants has not been showed significant difference. However, percentage electrolyte leakage increased up to 71.7% in the UC plants as against an increase to 55.5 and 52.2% in the TR lines L1 and L5 respectively. The percentage of electrolyte leakage in the UC plants under mannitol induced drought stress was up to 66.1% whereas the elevation in the electrolytic leakage was 48.7 and 41.6% respectively in the L1 and L5 TR lines as compared to the UC plants (Figure 3a).

The membrane damage due to the lipid peroxidation can be assessed by monitoring the formation of (Thiobarbituric acid reactive substances) TBARS due to the decomposition of the polyunsaturated fatty acids (PUFAs), Which is an important component of membrane lipids. We measured cellular TBARS concentration as one of the first consequences of oxidative stress, and also as an indicator of cellular damage. The MDA content in the UC and transgenic lines did not change significantly prior to the stress treatments. However, there was a significant increase in the MDA content in the UC plants compared to TR lines under salt and drought stress. UC plants showed 1.68 and 1.80 fold increment in the accumulation of MDA under salinity stress, whereas the fold increase in MDA accumulation due to drought stress in the UC plants were 1.63 and 1.68 as compared to the TR lines L1 and L5 respectively (Figure 3b).

During this study the proline content was also measured under...
the salinity and drought stress conditions. The TR lines L1 and L5 showed 3.2 and 3.4 times more proline accumulation respectively in comparison to the UC plants under saline stress, whereas the mannitol induced drought condition resulted into the 3.4 and 3.6 times higher proline accumulation in the TR lines L1 and L5 respectively in compared to UC plants (Figure 3c).

RWC is a parameter often used to assess the water retention capacity of plants. We assayed RWC in both UC and TR plants under non-stress and stress conditions. The RWC of UC plants was comparatively less as compared to the TR plants under drought and salt stress conditions. The RWC in leaf tissues of UC plants was reduced from 90% under non-stress to 48% and 56% in salt and drought stress conditions respectively whereas the decrease in RWC in the TR plants was from a control value of 90 and 91% (in lines L1 and L5) to 74% and 76% under salt stress and 71% and 74% under drought stress respectively (Figure 3d).

Discussion

The present study describes the introduction and expression of chickpea Lectin gene from into a widely grown cultivar of Indian mustard. The stringently transgenic plants were analysed through Southern blot analysis, which demonstrated that the transgenic lines were mostly containing a single copy of the transgene. The differential transcript expression profile of lectin observed between the different transgenic plants may be due to position effects of the transgene integration as the transgenes has integrated at different sites on the plant genome [29]. It is therefore, mostly desired to have single copy of candidate gene in transgenic lines.

Yield losses due to different abiotic and biotic stress are a serious problem in the cultivation of this crop [6]. The antifungal role of plant lectins due to their affinities to the carbohydrate are well documented in the scientific findings against several plant fungal phytopathogens [17,18]. The number and the size of lesions are important determiners for the degree of resistance to the leaf blight disease in Brassica species [24]. It is also reported the disease severity of Alternaria leaf blight caused by A. brassicae on the basis of the development of new lesions along with their expansion rate in terms of area and dimension in B. juncea plant [31] the present study the severity of disease in the terms of number and area of lesion were assessed. Fewer numbers of lesions were recorded on the leaves of TR lines as compared to the UC plants after the fungal infection caused by A. brassicae. Further the expansion rate of lesions was higher in the UC plants with respect to the transgenic lines. Srivastava and Srivastava reported that A. brassicae produces polygalacturonase and cellulases to degrade the cell wall of host plants [30]. It is well documented fact of research findings about the high avidity binding of lectins with the carbohydrate ligands present on the microbial surfaces. This high avidity binding causes the activation of opsonisation processes by the lectins by which the lectins interact with the phagocytic cells membrane receptors which lead to the stimulation of immune response. In view of the above findings, it can be conclude that, due to the interaction between the lectin and carbohydrates moiety on the fungal wall which resulted into the hypersensitive responses and opsonization which causes to the restriction of new lesion formation and reduction in the lesion area expansion on the leaves of transgenic plants compared to the UC plants. Reduction in the number and area of necrotic lesions are important marker of disease resistance in case of fungal infection in plant species.

Production of reactive oxygen species (ROS) is one of important manifestation of the abiotic and biotic stress conditions. To minimize the ameliorative effect of the ROS toxic metabolite, the plant produces...
different non-enzymatic effecter molecules. Relative tolerance of UC and TR plants to these stresses was assessed by measuring different parameters viz., electrolyte leakage, RWC, accumulation of MDA and proline [33]. Maintenance of high water content is an important marker of stress tolerance in plants. The results of the present study showed that RWC in TR lines L1 and L5 maintained at significant higher levels as compared to UC plants where it is decline due to imposed stress conditions. Bhushan et al. reported that lectin was expressed under stress condition and may be involved in the stabilization of the cytoskeleton structure under stress conditions [34]. Coefficient of lectin activity was increased by 2-15 times during the high temperature, osmotic and salinity stress in oil seed flax. The development of resistance by plants against abiotic stresses depends on the location of lectins in cell organelles. During the adaptation to stress the specificity of cytosolic and vacuolar lectins for carbohydrate are changed, such as total soluble lectin exhibit capacity to binding mannose and xylose, to saline stress galactose, glucose, and glucosamine. The candidate gene chickpea lectin was cloned under the CaMV 35S promoter which constitutively expresses the lectin which was evident with the differential transcript expression. The constitutive expression of lectin might be responsible for maintenance of the cellular pool of lectin which could be regarded as the suppressor of the stress response by direct participation with the membrane modifications in their quantitative and qualitative characteristics. Moreover it can be suggested that, the lectins may be regarded as drivers for plants to adapt various abiotic stresses. The increased electrolyte leakage under stress conditions in case of UC plants suggested much severe membrane damage compared to TR lines. The difference in the membrane damage was also evident in the higher MDA content in UC in comparison to TR lines. MDA accumulates as a result of lipid peroxidation, which is an effective indicator of oxidative damage. Therefore, it may be concluded that, lowering in the MDA content in the transgenic lines is resulted due to expression of lectin which is responsible for more stability of the cellular cytoskeleton structure in transgenic lines as compared to the untransformed control plants.

Our analyses also shows that lectin genes have been involved in biotic/abiotic stress regulations and tandem/segmental duplications may be regarded as drivers for plants to adapt various environmental stresses through duplication followed by expression divergence. In conclusion, our work demonstrates the generation of an economically important oilseed crop *Brassica juncea* having broad spectrum resistance against fungal pathogens and in conferring tolerance against salinity and drought stress by transgenic expression of chickpea lectin. This could be a promising candidate to reduce the yield loss caused by the salinity, drought and Alternaria leaf blight disease and also serve as an alternate option for crop management and sustainable agriculture.
