Recombination of H and He in Yang-Mills Gravity

Daniel Katz

November 3, 2014

Abstract

We investigate some aspects of the thermal history of the early universe according to Yang-Mills Gravity (YMG); a gauge theory of gravity set in flat spacetime. Specifically, equations for the ionization fractions of hydrogen and singly ionized helium during the recombination epoch are deduced analytically and then solved numerically. By considering several approximations we find that the presence of primordial helium and its interaction with Lyman series photons has a much stronger effect on the overall free electron density in YMG than it does in the standard, General Relativity (GR) based, model. Compared to the standard model recombination happens over a much larger range of temperatures, although there is still a very sharp temperature of last scattering around 2000 K. Since the ionization history of the universe is not directly observable we discuss how one may use it to predict the CMB power spectrum and thus test YMG. This topic will be explored in detail in an upcoming paper.

1 Introduction

The prediction [1] and subsequent discovery [2] of the Cosmic Microwave Background (CMB) radiation is some of the most compelling evidence in favor of the Big Bang theory of cosmic origins. General Relativity (GR), combined as needed with electro- and thermodynamics, does a more than adequate job of explaining the majority of observed astrophysical phenomena such as gravitational lensing, periapsis precession, the existence and properties of the CMB, and the relative abundances of light elements in the universe. The first two are examples of what can be done with a point-source solution to Einstein’s field equations (EFE) while the latter are typically accounted for by a “whole-universe” solution via the FLRW metric. As useful and accurate as GR is, however, there are many compelling reasons to look beyond it for a more complete description of gravity. Chief among these is GR’s utter incompatibility with quantum field theory [3]. There are also issues with GR both predicting the existence of singularities like black holes and the Big Bang and its own breakdown in treating them [4]. Because of this, alternative theories of gravity (usually quantum in nature) abound in the literature. In this article we consider the early thermal history of the universe according to one of them; Yang-Mills Gravity (YMG). In particular we analyze the recombination epoch. The same physics of an expanding plasma involved in the standard GR based approach applies to our treatment. However, we will see that the presence of helium makes a much more significant contribution to the evolution of the free electron density than it does in GR. As we obtain and present numerical results on ionization fractions for hydrogen and helium we will compare them quantitatively with standard results and find that, while they agree on the order of magnitude there is considerable disagreement in the details. For each ionization history we will calculate a photon visibility function which gives the probability that a given photon last scattered at the specified temperature. The fractional ionizations are not measurable quantities themselves, but the visibility functions they dictate in turn can be used to predict the angular power spectrum of the CMB. Calculating this power spectrum requires first working out a general theory of small fluctuations in an otherwise homogeneous isotropic universe described by YMG. Such a formalism is the motivation for this work but is itself still a work in progress.

This is not meant to be a review article on the subject, however, because YMG is largely unknown we will expound its principles and some of its consequences here for the readers’ convenience. More information can be found in [5,6,7]. Unless otherwise specified we will be using units where $c = \hbar = 1$ throughout.
2 Yang-Mills Gravity

YMG is a gauge theory set in flat (Minkowski) spacetime. As with all gauge theories its base is a group, which in our case is the group of all 4-dimensional spacetime translations which we’ll call $T_4$. Physics is already invariant under global $T_4$ transformations, so we impose upon it the further restriction of being invariant under local infinitesimal translations. Explicitly, we want nothing to change physically under the transformation

$$x^\mu \rightarrow x^\mu + \Lambda^\mu(x)$$

where $\Lambda^\mu$ is infinitesimal and behaves as nicely as we need it to mathematically but is otherwise arbitrary.

Obviously, the Lagrangians (and hence the equations of motion) for most systems are not going to be invariant under eqn 1. Using the formalism of Yang and Mills [8] (for which this theory is named) we can impose almost whatever local symmetry we like at the expense of adding a gauge field to the system. To do so we note that the generators of $T_4$ are $\partial_\mu$ and so $T_4$ is abelian, which makes dealing with it somewhat easier. On the other hand, its generators carry Lorentz indices so we cannot suppress them when expressing the $T_4$ gauge covariant derivative

$$\partial_\mu \rightarrow D_\mu = \partial_\mu + g\phi^\mu_\nu \partial_\nu$$

where $g$ is a coupling constant to be determined later and $\phi^\mu_\nu$ is the (symmetric) tensor field associated with local $T_4$ symmetry. To clarify, the gauge field is a tensor field in this case because the index of the group generators is itself a spacetime index and so the field needs to carry two such indices. So far it is not obvious that this theory describes gravity, although two hints emerge: 1) the covariant derivative is its own complex conjugate, so whatever force is mediated by $\phi^\mu_\nu$ has only attractive modes; and 2) the quanta of a tensor field can have spin 2, in agreement with general expectations for the graviton.

For any Lagrangian we can make the replacement of eqn 2 and obtain a local $T_4$ invariant version of that Lagrangian. This can in turn be separated into the original Lagrangian plus a coupling term which describes how $\phi^\mu_\nu$ interacts with other particles in the system. For this to be useful we’ll need to know the dynamics of $\phi^\mu_\nu$ itself. We construct the simplest possible Lagrangian density for our gauge field as follows. The gauge field strength is represented by the commutator of the covariant derivative with itself:

$$[D^\mu, D^\nu] = C^\mu_\nu^\alpha \partial_\alpha$$

$$C^\mu_\nu^\alpha = J^\mu_\sigma \partial_\sigma J^\nu_\alpha - J^\nu_\sigma \partial_\sigma J^\mu_\alpha$$

$$J^\mu_\nu = \eta^\mu_\nu + g\phi^\mu_\nu.$$ 

Here $C^\mu_\nu^\alpha$ is the field strength, $\eta^\mu_\nu$ is the Minkowski metric, and $J^\mu_\nu$ is a symbol which is often easier to work with than $\phi^\mu_\nu$ directly, defined for convenience. In this paper we will stick with $\eta^\mu_\nu$ as our background metric, but this is not required. Any geometrically flat metric tensor, i.e. one for which the Reimann curvature tensor vanishes, would do as well. The metric chosen must correspond to zero curvature because flat spacetime is an assumption of YMG. If another flat metric, say $P^\mu_\nu$, is chosen then the partial derivatives in eqns 2 and 3 need to be replaced with covariant derivatives with respect to $P^\mu_\nu$.

The simplest Lagrangian density we can construct for $\phi^\mu_\nu$ is a linear combination of all the quadratic contractions of the field strength $C^\mu_\nu^\alpha$. There are nearly a hundred of these but, because of the symmetry properties of $C^\mu_\nu^\alpha$, all but two of them are linearly dependent. Thus, we take the Lagrangian density for $\phi^\mu_\nu$ to be

$$L_\phi = \frac{1}{2g^2}(C^\mu_\nu_\alpha C_\nu^\mu_\alpha - C_\mu^\alpha C_\nu^\beta)$$

so the action of a matter system interacting with $\phi^\mu_\nu$ is

$$S = \int (L_\phi + L_{matter})d^4x.$$

where $L_{matter}$ describes whatever particles and/or fields are involved and has all its partial derivatives replaced by $T_4$ gauge covariant derivatives. Actually the combined Lagrangian density is often not $T_4$ invariant, but when it fails to be so it varies only by a 4-divergence. This means that the action, and
that eqn 5 is stationary gives the equations of motion for \( \phi \). In this paper, we shall decline to choose a gauge to make the equations a little bit simpler. Insisting chosen and imposed via a gauge fixing term in \( L \) the coupling constant linearized Einstein’s field equations [5]. Requiring that we recover Newtonian gravity in this limit fixes be considered a theory of gravity; in the weak field limit eqn 6 becomes mathematically identical to the where \( T \) the equations of motion, are 

\[
\begin{align*}
T^{\mu\nu} & = \partial_\lambda (J^\lambda_{\mu\nu} - J^\lambda_{\mu} C^\alpha_{\beta\lambda} \eta^{\nu\alpha} + C^\alpha_{\beta\nu} J^\lambda_{\mu\alpha}) \\
& \quad - C^\alpha_{\beta\nu} \partial_\rho J^\rho_{\mu\alpha} - C^\alpha_{\beta\nu} \partial_\lambda J^\lambda_{\mu\alpha} - C^\lambda_{\beta\nu} \partial_\rho J^\rho_{\mu\lambda} - C^\lambda_{\beta\nu} \partial_\lambda J^\lambda_{\mu\rho},
\end{align*}
\]

(6)

where \( T^{\mu\nu} \) contains all the terms involving matter fields from \( L_{\text{matter}} \). Now we can see why YMG might be considered a theory of gravity; in the weak field limit eqn [6] becomes mathematically identical to the linearized Einstein field equations [5]. Requiring that we recover Newtonian gravity in this limit fixes the coupling constant \( g = \sqrt{8\pi G} \). Formal mathematical similarity to gravitational equations by its self is not enough to be sure that YMG describes the gravitational interaction. We will now show with an example that interaction with the field \( \phi^{\mu\nu} \) modifies the trajectories of objects just like they were in a gravitational field.

If \( L_{\text{matter}} \) is the usual Lagrangian density for electrodynamics with \( T^4_{\text{gauge}} \) covariant derivatives then the equations of motion obtained by varying eqn [5] with respect to the electromagnetic potential \( A^\mu \) are

\[
(\partial_\mu J^\mu_{\alpha\beta} + \partial_\nu J^\nu_{\alpha\beta})(D^\alpha A^\beta - D^\beta A^\alpha) = 0.
\]

Assume an eikonal form for the potential \( A^\mu = a^\mu \exp(i S) \) with \( a^\mu \) a constant polarization vector and \( S \) the electromagnetic action. Now we consider the classical limit of these equations (corresponding to ray optics) by taking \(|\partial_\mu S| \gg |\phi^{\mu\nu}|\) we obtain

\[
G^{\mu\nu} \partial_\mu S \partial_\nu S = 0, \quad G^{\mu\nu} = J^\mu_{\alpha} J^\nu_{\alpha}.
\]

(8)

The tensor \( G^{\mu\nu} \) is the effective metric tensor of YMG. It is a metric in the sense that it modifies the trajectories of classical objects just as a curved geometric metric tensor would. On the other hand it is merely effective because its derivation in no way invoked geometry, and the true geometry of spacetime is taken in this theory to be flat. Although we have only demonstrated that the effective metric appears in the optical limit of electromagnetism, it also appears in the macroscopic-object limit of the Dirac equation for Fermions with \( T^4_{\text{gauge}} \) covariant derivatives [3]. In every example considered thus far the effective metric tensor, with the same form as the one in eqn [7] appears in the classical limit of equations of motion derived from actions like [4]. Based on this we see that YMG describes gravity as an emergent phenomena. Microscopic objects interact with it via the full equations of motion, but the cumulative effect of these interactions is to mimic curved spacetime on large scales. We note, for fairness, that no general proof yet exists that the effective metric will always show up for \( \phi^{\mu\nu} \) coupled to an arbitrary field.

We conclude our review of YMG by noting that it seems to have the same predictive power as GR on large scales. Gravitational radiation, periapsis precession, and gravitational lensing are all predicted by YMG and these predictions agree with present observations [7]. In all cases studied so far the results produced are the same as those from GR but with small corrections. This is not too surprising since the theories agree exactly in the weak field limit. The corrections to GR offered by YMG are obscured by present-day experimental uncertainties. They are large enough, however, that one can reasonably expect that experimental precision will someday be able to measure them (e.g. they are not Planck-scale corrections).

3 FLRW Cosmology in YMG

The solar-system scale phenomena mentioned above are treated in YMG by solving eqn [6] with \( T^{00} = m\delta(r) \) and all other components of \( T^{\mu\nu} \) equal to zero. The static spherically symmetric solution is not available in closed form as it is for GR (i.e. the Schwarzschild solution) but rather has to be found by an approximate ansatz solution. In those cases the solution obtained is a series of inverse powers of \( r \) with only the first coefficient chosen to reproduce Newtonian gravity. To start doing cosmology with YMG we take the same basic approach: assume the effective metric has the form that GR’s metric takes. In this case that amounts to assuming that \( G^{\mu\nu} \) from eqn [5] is of the Robertson-Walker (RW)
Table 1: Scale factors for universes dominated by one type of substance. In each case YMG predicts a slightly slower growing universe than GR does. In the dark energy row, $H$ is assumed constant and $\beta$ is a time-independent abbreviation proportional to the cosmological constant; see [9] for details.

| Substance     | GR         | YMG         |
|---------------|------------|-------------|
| Matter        | $a \propto t^{2/3}$ | $a \propto t^{2/5}$ |
| Radiation     | $a \propto t^{1/2}$ | $a \propto t^{1/3}$ |
| Dark Energy   | $a \propto e^{Ht}$ | $a \propto \cosh(\beta t)$ |

form $\text{diag}(1, -a^2, -a^2, -a^2)$ where the scale factor $a$ is a function of comoving time alone. Since the effective metric governs the motion of macroscopic objects, the same arguments that lead to the RW form for GR’s curved spacetime metric from the assumptions of homogeneity and isotropy will do so for the effective metric as well.

Taking the RW metric as an ansatz solution for eqn 6 we arrive at YMG’s analogue of the Friedmann equations [9]

$$H = \frac{H_0}{2a} \sqrt{\Omega_m/a^3 + \Omega_r/a^4 + \Omega_\Lambda}$$

where $H = \dot{a}/a$ is Hubble’s parameter, $H_0$ its value at the present time, $a$ is the scale factor normalized to unity at the present time, and $\Omega_m$, $\Omega_r$, and $\Omega_\Lambda$ are the fractional densities of matter (baryonic and dark), radiation and relativistic particles, and vacuum energy, respectively. Equation 9 is the basis for studying cosmology with YMG, just as the Friedmann equations are for GR. Unlike the Friedmann equations, ours has no ingress for a possible curvature term since $K = 0$ is a fundamental assumption of YMG. This is not a handicap, though, as observations pretty well rule out $K \neq 0$ [10, 11]. Just as in GR it turns out that there are several special cases for which eqn [9] can be solved exactly. Table 1 shows these solutions up to an overall normalization factor as well as the corresponding standard solutions for comparison.

Because $a \propto T^{-1}$ the slower growth as a function of time in YMG corresponds to faster growth as a function of temperature. We will see later that this gives some high temperature photons a better chance of escaping reabsorption into the primeval plasma. We note in passing that a constant vacuum energy produces more-or-less exponential growth in YMG meaning that the theory should be able to accommodate an early era of extremely rapid inflation due to one or more scalar fields. Inflation in YMG has not yet been studied in detail and in any case is beyond the scope of this article.

### 4 Ionization Fractions

The radiation dominated solution to the Friedmann-like equation [9] begins as a singularity, so the qualitative aspects of the Big Bang theory are preserved in YMG. Because of this we expect that at some point the hot plasma of mostly protons and electrons will cool sufficiently to allow neutral hydrogen atoms to form and the probability of it scattering with the background photons will plummet. This process itself happened long ago and thus is not observable. However, its influence on the background photon bath is observable by directly measuring these photons; the CMB. Using the ionization history of the universe to predict anisotropies in the CMB is a complicated problem, and its application in YMG is a work in progress. Of course, a necessary first step is to work out what the ionization history looks like, which is the main topic of this paper. Big Bang nucleosynthesis has not yet been studied in the context of YMG so we begin by assuming that, in accordance with observations, the primordial plasma was 76% protons, 24% helium nuclei, and enough electrons to make it all electrically neutral [12]. In addition we take the standard values of $\Omega_b = 0.046$ and $\Omega_m = 0.240$ for the fractional densities of baryonic matter and baryonic plus dark matter, respectively.

To asses the relative importance of helium in the recombination process we will consider two different models: one which ignores helium and one which does not. The first model is based on the classic one due to Peebles [13], but where he uses the total rate of Lyman $\alpha$ emission directly we skirt around it by

| Substance     | GR         | YMG         |
|---------------|------------|-------------|
| Matter        | $a \propto t^{2/3}$ | $a \propto t^{2/5}$ |
| Radiation     | $a \propto t^{1/2}$ | $a \propto t^{1/3}$ |
| Dark Energy   | $a \propto e^{Ht}$ | $a \propto \cosh(\beta t)$ |
assuming that changes in the number density of excited hydrogen due to recombination and reionization are exactly cancelled out by transitions to and from the ground state. In exchange for not having to deal with the total Lyman $\alpha$ production rate we must instead calculate the escape probability for $\alpha$’s, that is, the probability that a photon emitted in $2p \rightarrow 1s + \gamma$ will never be reabsorbed by another ground state hydrogen atom [14]. The result is equivalent to that of Peebles. Although the result is standard [15] it is worth rederiving here because it uses a multitude of approximations. These approximations are known to be valid in GR but we need to make sure that they remain so in YMG rather than just accepting them.

Let $n_B, n = 0.76n_B, n_e, n_{nl}$, and $X_i = n_i/n$ be the number densities of baryons, ionized and neutral hydrogen atoms, free electrons, hydrogen atoms in the $nl$ state, and the fractional abundance of $i = e, nl$ relative to hydrogen, respectively. If we assume that the excited states are all in thermal equilibrium

$$n_{nl} = (2I + 1)n_{2s}e^{(E_2 - E_{n_i})/kT}$$  \hspace{1cm} (10)

where $E_n$ is the binding energy of the $n^{th}$ excited state and $k$ is Boltzmann’s constant. Because the excited states are all in thermal equilibrium with each other de-excitation to the ground state from states having $n > 2$ is very inefficient. Thus, in addition to the ground state $1s$ we need only include the $2s$ and $2p$ states in our calculation. The number density of free electrons is reduced by the recombination of hydrogen atoms at a rate proportional to both components; free electrons and free protons. To have charge neutrality means $n_e = n_p$. Likewise, free electrons are produced by photons from $2s \rightarrow 1s + \gamma$ transitions at a rate proportional to $n_{2s}$ (because, as we have stated, higher order transitions are inefficient). Symbolically this reads

$$\frac{d}{dt} \left( \frac{n_e}{n} \right) = -\alpha \frac{n_e^2}{n} + \beta \frac{n_{2s}}{n}$$  \hspace{1cm} (11)

where $\alpha$ is the case B recombination coefficient and $\beta$ the reionization coefficient. Both $\alpha$ and $\beta$ are functions of temperature alone and are related to each other by the equilibrium condition

$$\frac{\beta}{\alpha} = \left( \frac{m_e kT}{2\pi} \right)^{3/2} e^{-E_2/kT}$$  \hspace{1cm} (12)

where $m_e$ is the mass of the electron. Again because the excited states are in equilibrium increases in the free electron density are enhanced by decays from $n = 2$ states and impeded by excitations from ground to $n = 2$ states. Thus,

$$\alpha n_e^2 - \beta n_{2s} = (\Gamma_{2s} + 3\Gamma_{2p})n_{2s} - \Gamma_{1s}n_{1s}$$  \hspace{1cm} (13)

where $\Gamma_{1s}, \Gamma_{2s}$, and $\Gamma_{2p}$ are the rates of $1s + \gamma \rightarrow 2s$ or $2p$, $2s \rightarrow 1s + \gamma + \gamma$, and $2p \rightarrow 1s + \gamma$, respectively. We neglect the two-photon decay of the $2p$ state because it is much slower than that of the $2s$ state [10]. In the above equation $P$ is the probability that a $2p \rightarrow 1s + \gamma$ photon will escape the plasma without exciting a neighbouring atom, which we will calculate soon. We will see that recombination begins at a higher temperature here than it does in the standard model, but this temperature is still quite a bit smaller than $(E_2 - E_1)/k \approx 22,000 \ K$. To a good approximation then, we can write

$$n = n_{1s} + 4n_{2s}.$$  \hspace{1cm} (14)

In equilibrium the right-hand-side of eqn [13] vanishes and this yields a relationship between all of our decay/excitation rates:

$$\frac{\Gamma_{1s}}{\Gamma_{2s} + 3\Gamma_{2p}} = e^{(E_2 - E_1)/kT}.$$  \hspace{1cm} (15)

The purpose of deriving the last three equations was to be able to write eqn [11] as a differential equation of a single unknown function. All that remains is to calculate the photon escape probability. Without making any further approximations this is

$$P(t) = \int_{-\infty}^{\infty} d\omega \mathcal{P}(\omega) \exp \left[ -\int_t^{\infty} dt' n_{1s}(t') \left( \frac{3}{2} \left( \frac{2\pi^2 \Gamma_{2p}}{k^2} \right) \mathcal{P} \left( \omega \frac{a(t)}{a(t')} \right) \right) \right]$$  \hspace{1cm} (16)

where we have used the Breit-Wigner formula for the photon-hydrogen resonant cross-section, $k_\alpha = (E_1 - E_2)$ is the Lyman $\alpha$ wavenumber, and

$$\mathcal{P}(\omega) = \frac{\Gamma_{2p}}{2\pi} \left( \frac{1}{(\omega - \omega_\alpha)^2 + \Gamma_{2p}^2/4} \right)$$  \hspace{1cm} (17)
(\omega_\alpha \text{ is the frequency corresponding to } k_\alpha). \text{ It would be quite difficult to carry out the integrals in } \text{ (they stand, but several approximations can be made with only a minimal loss of precision. First, because recombination happened in the distant past the time scale on which a photon may be absorbed is much less than } 1/H_0 \text{ so we can change the argument of } n_{1s} \text{ from } t' \text{ to } t. \text{ For the same reason we can Taylor expand } a(t)/a(t') \approx 1 - H(t)(t' - t). \text{ After changing variables from } t' \text{ to } \omega' = (1 - H(t)(t' - t))/\omega \text{ the escape probability is}

\begin{equation}
    P(t) = \int_0^\infty d\omega P(\omega) \exp \left[ -\frac{3\pi^2 \Gamma_{2p} n_{1s}}{\omega k^3 H} \right] \int_0^\omega \frac{P(\omega')d\omega'}{\omega'}. \tag{18}
\end{equation}

The probability density } P \text{ is nearly a delta function of } \omega_\alpha \text{ so we can replace the factor of } 1/\omega \text{ with } 1/\omega_\alpha. \text{ Now all the integrals can be evaluated exactly, giving}

\begin{equation}
    P(t) = \frac{1 - e^{-x}}{x}, \quad x = \frac{3\pi^2 \Gamma_{2p} n_{1s}}{\omega_\alpha^3 H}. \tag{19}
\end{equation}

Plugging in numbers we see that } x \text{ is large over our whole range of interest so we can drop the decaying exponential in } P(t). \text{ Rearranging the result reveals that we didn’t need to know } \Gamma_{2p} \text{ after all;}

\begin{equation}
    3P\Gamma_{2p} = \frac{8\pi H\omega_\alpha^3}{n_{1s}}. \tag{20}
\end{equation}

At last, we can combine eqns \text{ [13, 14, 15] and [20]} to put eqn \text{ [11]} in the desired form. For convenience we replace time with temperature as the independent variable, and for simplicity we drop several decaying exponentials which are negligible for the temperatures we’re interested in. The result is

\begin{equation}
    \frac{dX_e}{dT} = \frac{\alpha n}{H^2} \left( \frac{\beta}{n_{1s} + 8\pi H\omega_\alpha^3/[(1 - X_e)]} \right)^{-1} \left( \left( \frac{X_e}{1 - X_e} \right)^{S} = \left( \frac{1 - X_e}{S} \right) \right) \tag{21}
\end{equation}

where } S = n(m_e kT/2\pi)^{-3/2} \exp(E_1/kT) \text{ is so named because it is the function which appears in the Saha equation for a similar non-expanding hydrogen plasma. Because of the relationship between } \alpha \text{ and } \beta \text{ we only need to specify one of them. Péguegnot, Petitjean, and Boisson } \text{ [17]} \text{ have compiled a large amount of atomic data and found that}

\begin{equation}
    \alpha(t) = F_H \frac{a(t)^b}{1 + e^{d/T}} \tag{22}
\end{equation}

fits very well over a wide range of temperatures, both far below and far above our region of interest. \text{ (The values of the parameters } F_H, a, b, c, \text{ and } d \text{ are given in table } \text{ [2] and } t = T/10^4 \text{ K). With all of this at hand we are ready to solve eqn } \text{ [21]} \text{ numerically, using the Saha equilibrium value for } X_e \text{ as the initial condition. This is yet another approximation, since the hydrogen plasma can’t be in Saha equilibrium while it’s in an expanding universe, but both values (the Saha and true values) are so close to unity at our starting temperature that it hardly matters. Figure } \text{ [1]} \text{ shows the numerical solution to eqn } \text{ [21]} \text{ along with the standard result from a GR based treatment for reference. }

\text{ As might have been expected from the slower expansion rates (see table } \text{ [1]} \text{ of YMG, the recombination of free electrons and protons into neutral hydrogen atoms is somewhat delayed. In the figure we have to specify that the blue curve is for the hydrogen-only model in YMG because later on we will consider another model. No such distinction is necessary for the standard result because the influence of helium on the recombination temperature is small enough to not be easily noticeable on a linear-scale graph over the given range.}

\text{ Having seen the timeline for recombination without helium we are ready to appreciate its importance. To maximize the level of detail we will use the effective three-level model of Seager } \text{ et al } \text{ [18, 19]} \text{ based on their enormous 300-level simulation. To reduce their system of thousands of ODE’s to just three, they absorb a lot of information into the effective recombination and reionization coefficients } \alpha \text{ and } \beta. \text{ Of course, in our model, the Hubble parameter follows a different evolution equation but the thermal physics is the same. The ionic fractions } X_H, \text{ } X_{He}, \text{ (hydrogen and helium II) and } T_M, \text{ the temperature of non-relativistic matter, are the dependent variables to be solved for while } T, \text{ the temperature of the radiation background, is the sole independent variable. We also take } T, \text{ rather than } T_M, \text{ as the driving}
force behind cosmic expansion, that is, \(H = H(T)\). Using \(X_e = 0.76 \times X_H + 0.24 \times X_{He}\) the equations coupling \(X_H\), \(X_{He}\), and \(T_M\) are

\[
\frac{dX_H}{dT} = \left( X_e X_H n_H \alpha_H - \beta_H (1 - X_H) e^{-\omega_{H2s}/kT_M} \right) \times \frac{1 + K_H \Gamma_{H2s} n_H (1 - X_H)}{HT (1 + K_H (\Gamma_{H2s} + \beta_H) n_H (1 - X_H))}
\]

\[
\frac{dX_{He}}{dT} = \left( X_{He} X_e n_H \alpha_{He} - \beta_{He} (f_{He} - X_{He}) e^{-\omega_{He2s}/kT_M} \right) \times \frac{1 + K_{He} \Gamma_{He2s} n_H (f_{He} - X_{He}) e^{-\omega_{ps}/kT_M}}{HT (1 + K_{He} (\Gamma_{He2s} + \beta_{He}) n_H (f_{He} - X_{He}) e^{-\omega_{ps}/kT_M})}
\]

\[
\frac{dT_M}{dT} = \frac{8 \sigma_T \pi R^3 T^3}{3 H m_e} \frac{X_e (T_M - T) + 2 T_M}{1 + f_{He} + X_e} \quad \text{cm}^{-3} \text{s}^{-1}
\] 

(23)

Here \(\alpha_{He}\) is an effective recombination coefficient which is fitted to incorporate the data from Seager’s 300-level model. It takes its form from Verner and Ferland [20] and is most valid between 4000 and 10,000 K but it is still very accurate down to 1000 K.

The functions \(K_H\) and \(K_{He}\) are shorthand for the cosmologically redshifted wavelengths of \(2p \rightarrow 1s\) photons from hydrogen and helium I, respectively: \(K_i = (8 \pi \omega_{i2p} H)^{-1}\), \(i = H, He\). Below, table 2 summarizes the constants and parameters in equations [22] [23] and eqn [24].

As recommended by Seager et al the parameters \(F_H\) and \(F_{He}\) are order unity fudge factors which absorb some of the error introduced in approximating a 300-level model by a 3-level model.

Solving eqns [23] yields the three functions \(X_H\), \(X_{He}\), and \(T_M\) of the radiation temperature, but we’re only interested in a certain linear combination of two of them: \(X_e = 0.76 X_H + 0.24 X_{He}\). This function, the fraction of free electrons, is plotted in figure 2.

The fact that accounting for singly-ionized helium changes the recombination rate so drastically tells us that, unlike in the standard model, the hydrogen and helium recombinations overlap significantly. Qualitatively this makes sense because the expansion rate of the universe is slower in YMG than it is in
Table 2: Definitions and values of the constants and parameters used in the recombination simulations. 1) To clarify, \( f_{He} = \frac{Y_p}{4(1 - Y_p)} \) where \( Y_p = 0.24 \) is the primordial helium abundance.
Figure 2: The fraction of free electrons, as a function of radiation temperature, according to YMG. This figure shows that the inclusion of helium into the calculation makes a substantial difference in the ionization history of the early universe. The first drop in the $H$ & $He$ model is the recombination of $HeII$ to $HeI$ and the second drop is the recombination of hydrogen.

GR. According to $a \propto T^{-1}$ expanding slower as a function of time means expanding faster as a function of temperature. Thus, at the (high) temperatures at which helium would normally finish recombining the expansion of the universe makes it more diffuse and so slows down the interaction rate. This means that both protons ($H^+$) and $HeII$ are competing for the same cloud of electrons over a wider range of temperatures. Once all the helium is done recombining, at around 2100 K, the remaining $H^+$ quickly captures the rest of the free electrons.

The details of how the universe transitioned from fully ionized to electrically neutral on large scales are different in YMG than they are in GR. Qualitatively the two are quite similar. In both cases recombination is significantly delayed, compared to static Saha equilibrium, by cosmic expansion. Also there is a specific temperature where virtually all of the recombination occurs. The theories differ in their prediction of what that temperature is and how long the transition takes. As we have stated before, the ionization history itself is not directly observable (we've missed it by billions of years) but it, along with a gravitational theory of small fluctuations in an expanding universe, predicts the power spectrum of the CMB. This prediction requires that we know the probability, as a function of temperature, that a given photon last scattered at that temperature before eventually being absorbed by one of our detectors: the visibility function.

5 Opacity & Visibility Functions

The optical depth of the hydrogen/helium plasma at some time $t$ is

$$\tau(t) = -\int_{t_0}^{t} \sigma T n_e(t') dt'$$  \hspace{1cm} (25)$$

where $n_e$ is the number density of free electrons and $t_0$ is the present time. Several reasonable approximations go into this definition. First, by using the Thomson cross-section we are ignoring relativistic collisions between electrons and photons. Over the temperature range on which we plan to use eqn 25 from 1000 K to 10,000 K this is thoroughly acceptable. Secondly, since only $n_e$ appears in eqn 25 we are neglecting the possibility of photons scattering off of neutral hydrogen and/or helium atoms. This is also a fine approximation because the probability of a photon scattering off of an electrically neutral particle is dwarfed by the probability of it scattering off a charged particle. We have calculated $n_e$ as a function
of temperature so it will be more convenient to change the variables of the integral in $\tau$ from $t$ to $T$, giving

$$\tau(T) = -\sigma_T \int_{T_0}^{T} \frac{n_e(T')}{H(T')}dT'$$

(26)

where $T_0 = 2.725$ K is the present temperature of the CMB. What we really want to do is identify the temperature of last scattering, and for that we invoke the visibility function [21]

$$F(T) = \left( \frac{d}{dT} e^{-\tau(T')} \right) \bigg|_{T' = T}$$

(27)

In the standard picture $F$ is very well fit by a Gaussian probability distribution with mean 2941 K and spread $\sigma = 248$ K [15]. The same cannot be said for our visibility function, which is shown in figure 3 for the hydrogen-only model and for the multilevel hydrogen & helium model.

Figure 3: The visibility functions, plotted in arbitrary units, versus temperature for the two models considered.

Again we see that the inclusion of helium in our calculations makes a huge difference. Not only does it push the visibility function’s peak to a lower temperature, it also makes the cut-off much sharper. The standard model result is not shown in figure 3 because it is much larger on the vertical scale and much smaller on the horizontal than the YMG visibility functions. Nevertheless we remark that it too has a high-temperature tail which decays slower than the one on the other side of the peak. The fact that our visibility functions have a cut-off means that YMG does predict that there is a temperature at which matter and radiation essentially decouple. We can understand the relatively high probability of last scattering at higher temperatures by recalling that the scale factor increases at a faster rate (compared to that of GR) at high temperatures. Some of the photons scattered at, say, 7000 K will be left stranded by this rapid expansion and never hit another atom (until we measure it).

6 Conclusions and Future Work

The discrepancy between the ionization history according to YMG and GR might be a cause for concern. After all, GR has been used very successfully to predict the power spectrum of the CMB. Using the visibility function in figure 3 with GR’s perturbation theory would necessarily lead to results contrary to observation. But YMG is a theory of gravity independent of GR and as such, deviations from perfect homogeneity and isotropy must be dealt with by perturbing the energy-momentum and RW effective metric tensors. Equation 6 then gives us the means to deduce the evolution of these perturbations. We have derived these perturbed equations and will use them, along with the usual theory of thermodynamics in
an expanding universe, to predict the power spectrum of the CMB, to be compared with observations. Conceptually this calculation would be very much like it is in GR. Technically, because of the large spread of the visibility function in YMG, we will be unable to make use of the “sudden decoupling” approximation.

We have shown that YMG predicts an era of recombination of neutral atoms from the primordial plasma. This process takes much longer in YMG than it does in GR, but both theories have a sharp cut-off in their cosmic visibility functions. Including helium in the recombination calculations of GR induces only very small corrections whereas it radically changes the dynamics in YMG. We understand this change as being due to a larger overlap between the eras of helium and hydrogen recombination. Our results disagree with the standard ones but are in any event not directly observable. Future work will use these results to predict the power spectrum of the CMB in order to test the validity of YMG.
