(Dated: present)

Particle-decaying states of the light nuclei \(^{11,12}\)N and \(^{12}\)O were studied using the invariant-mass method. The decay energies and intrinsic widths of a number of states were measured, and the momentum correlations of three-body decaying states were considered. A second \(2p\)-decaying \(2^+\) state of \(^{12}\)O was observed for the first time, and a higher energy \(^{12}\)O state was observed in the \(4p+2n\) decay channel. This \(4p+2n\) channel also contains contributions from fission-like decay paths, including \(^{6}\)Be\(_g\), \(^{16}\)Be\(_g\). Analogs to these states in \(^{12}\)O were found in \(^{12}\)N in the \(2p+10\)B and \(2p+\alpha+4\)Li channels. The momentum correlations for the prompt \(2p\) decay of \(^{12}\)O\(_g\)\(_s\) were found to be nearly identical to those of \(^{16}\)Ne\(_g\)\(_s\), and the correlations for the new \(2^+\) state were found to be consistent with sequential decay through excited states in \(^{11}\)N. The momentum correlations for the \(2^+\) state in \(^{12}\)O provide a new value for the \(^{11}\)N ground-state energy. The states in \(^{12}\)N/\(^{12}\)O that belong to the A=12 isobaric sextet do not deviate from the quadratic isobaric multiplet mass equation (IMME) form.

I. INTRODUCTION

Isotopes near and beyond the drip lines can show interesting properties such as spatially extended halos, prompt two-nucleon emission, and low-energy intruder states. They also present a theoretical challenge as coupling to the continuum needs to be included which can result in clusterization \(^1\) and the breaking of isospin symmetry due to Thomas-Ehrman effects \(^2,3\).

Experimentally, the invariant-mass method can play an important role in the study of such effects, finding new levels, and characterizing their decays. It is particularly useful in 3-body decays as the momentum correlations between the decay products can capture information about the decay dynamics and the structure of the parent states. These correlations can be characterized by a two-dimensional plot of kinematic relations between the decay fragments. High-statistics measurements of such plots for the democratic \(2p\) decay of the \(^{8}\)Be and \(^{16}\)Ne ground states have been made and successfully compared to three-body calculations \(^4,5\). For the intermediate case, \(^{12}\)O\(_g\)\(_s\), only a 1-dimensional distribution has been measured with lower statistics \(^6\).

The structure of \(^{11}\)N is important for excited \(^{12}\)O levels that sequentially \(2p\) decay. Knowledge of the energies, widths, and decay paths of these states will lead to better understanding of this sequential \(2p\) decay and constrain theoretical calculations.

The isobaric analog of \(^{12}\)O in \(^{12}\)N was also shown to undergo prompt \(2p\) decay to the isobaric analog state (IAS) in \(^{10}\)B \(^7\). This represented a second case of prompt \(2p\) decay from one IAS to another IAS, with the first case being \(^{8}\)B\(_{IAS}\) \(\rightarrow\) \(2p+^{6}\)Li\(_{IAS}\) \(^{8}\). It is interesting to determine if these analog \(2p\) decays have the same momentum correlations as their ground-state cousins. \(^{8}\)B\(_{IAS}\) is the analog of \(^{8}\)C\(_g\)\(_s\), which decays by two sets of prompt \(2p\) decays \(^8\). It is difficult to separate the protons from the two steps, making comparison of the analog \(2p\) decays difficult. On the other hand, \(^{12}\)O\(_g\)\(_s\) and its analog \(^{12}\)N\(_{IAS}\) present no such difficulties, as there is only one step of \(2p\) decay in both systems. It is also interesting to see if higher-lying analog states undergo prompt or sequential \(2p\) decay to the \(^{10}\)B\(_{IAS}\).

This work is part of a larger joint experimental and theoretical study of \(^{12}\)O and its neighbors with the aim of addressing these issues. The present paper mostly presents experimental results with comparisons to other experimental values and some previous theoretical predictions. Comparisons with predictions of the Gamow coupled-channel (GCC) method \(^10,11\) are given in Refs. \(^12,13\) and this work, and further comparisons will be elaborated on in future papers when the model is extended to include the dynamics of the \(2p\) decay.
II. EXPERIMENTAL METHODS

The data presented were obtained at the National Superconducting Cyclotron Laboratory at Michigan State University, which provided a $^{16}$O primary beam at 150 MeV/A. The primary beam bombarded a 193 mg/cm$^2$ $^9$Be target, and $^{13}$O fragments were selected by the A1900 magnetic separator. Upon extraction from the separator, this 69.5 MeV/A secondary beam had a purity of only 10%. To remove the substantial contamination, the beam was sent into an electromagnetic time-of-flight filter, the Radio Frequency Fragment Separator [14], and emerged with a purity of 80%. The final secondary beam impinging on a 1-mm-thick $^9$Be target and the charged particles produced were detected in the High Resolution Array (HiRA) [12], consisting of 14 $\Delta E$-E [Si-CsI(Tl)] telescopes 85 cm downstream of the target. The array subtended a polar angular range of 2.1$^\circ$ to 12.4$^\circ$. Each telescope consisted of a 1.5-mm-thick, double-sided Si strip $\Delta E$ detector followed by a 4-cm-thick, CsI(Tl) E detector. The $\Delta E$ detectors are 6.4 cm $\times$ 6.4 cm in area, with each of the faces divided into 32 strips. Each E detector consisted of four separate CsI(Tl) elements each spanning a quadrant of the preceding Si detector. Signals produced in the 896 Si strips were processed with the HINP16C chip electronics [16].

The energy calibration of the Si detectors was obtained with a $^{232}$U $\alpha$-particle source. The particle-dependent energy calibrations of the CsI(Tl) detectors were achieved with cocktail beams selected with the A1900 separator. These included protons (80 MeV), $N=Z$ fragments ($E/A=80$ MeV), and $^9$C ($E/A=82.9$ MeV). Lower-energy points were obtained using 2.2-, 4.9-, and 9.6-mm-thick Al degraders. Calibrations for $^{10}$C and $^{9}$Be fragments were obtained from interpolating and extrapolating these results.

For the normalization of cross sections, the beam particles were counted using a thin plastic-scintillator foil at the exit of the Radio Frequency Fragment Separator. The purity of the beam and the beam flux loss due to its transport to the target were determined periodically in the experiment by temporarily placing a CsI(Tl) detector in the target position. These fluxes were also corrected for the detector dead time measured with a random pulse generator.

III. INVARIANT-MASS METHOD

In the decay of a parent state into two or more pieces, the mass of the parent can be obtained from the invariant mass of the decay products. Experimentally we measure the invariant mass $M_{inv}$ of the charged particles detected in the HiRA array. Rather than using the $M_{inv}$, it is often more convenient to use the total kinetic energy ($E_T$) of the fragments in the center-of-mass frame of these fragments

$$E_T = M_{inv} - \sum M_i$$

This quantity only represents the true excitation energy if all of the detected fragments were produced in their ground states rather than particle-stable excited states. For some of the detected fragments considered in this paper ($^6$Li, $^{10}$B, and $^{10}$C), there are $\gamma$-decaying excited states, and thus the true excitation energy is obtained by adding the sum of the $\gamma$-rays energies, i.e.

$$E^* = E_{inv} + \sum E_{\gamma}.$$ Both $^6$Li and $^{10}$C have only one $\gamma$-decaying excited state, limiting the number of possible excitation values for an event that includes one of these fragments.

The largest degrading factor to the invariant-mass resolution is from the energy loss of the decay fragments as they leave the target material [17]. In particular it is the change in the relative velocities of the fragments that

![FIG. 1: Excitation-energy spectra of calibration peaks for (a) the first 2p-decaying levels of $^{13}$O and (b) the first two excited states of $^{12}$N reconstructed from transversely decaying 2p+$^{13}$C and p+$^{14}$C events respectively. The solid red curves show the results of Monte Carlo simulations incorporating the detector response and known level properties. The blue dashed curves are fitted estimations of the background. Total decay energy spectra (c), (d) of $^{12}$O reconstructed from transversely decaying 2p+$^{13}$C events. (c) shows a fit at the upper limit of the uncertainty for the $0^+_1$ width while (d) shows the fit at the lower limit. The red solid curve shows the summed results of Monte-Carlo simulations of each resonance, shown by the solid green curves. The blue dashed curve shows the fitted background. A $|\cos \theta_C| < 0.2$ gate was applied for all spectra.](image-url)
is important, with protons having much smaller velocity losses compared to the heavier cores. The difference in the velocity losses depends on the interaction depth in the target material, which is not known. However we make an average correction to the velocities by assuming the reaction occurs in the center of the target material, which gives the correct average invariant mass. The contribution of this effect to the resolution can be minimized by selecting events based on the emission angle of the recoil. The gates used are specified in the figure captions.

Peaks found in the experimental invariant-mass spectra were fit to extract the resonance energy and intrinsic width assuming some intrinsic line shape. The experimental resolution and efficiency is included via Monte-Carlo simulation \cite{17}. These simulations are benchmarked by comparison to well-known narrow resonances with high statistics.

Figures 1(a) and (b) show the excitation-energy spectra for particle-unbound states of $^{12}$O from detected $2p^{+10}$C events and of $^{12}$N from $p^{+11}$C events, respectively. The curves show fits assuming Breit-Wigner intrinsic line shapes. The fitted parameters for the $2^+_1$ and $2^+_1$ states of $^{12}$N are shown in Table I and compared to the ENSDF values. The reported width of the $2^+_1$ state is much smaller than the experimental resolution, so the width of this peak is essentially only from the experimental resolution. The simulated peak calculated with $\Gamma=0$ reproduces the observed peak correctly.

The peaks in the $2p^{+11}$C spectrum have only been seen in one previous study \cite{18}. Again we obtained excellent reproduction of these peaks with $\Gamma=0$ as their width is also dominated by the experimental resolution. The centroid for the lower-energy peak is consistent with the previous value, while the higher-energy is slightly higher (see Table II). Based on past experience, we expect a systematic error of around 10 keV \cite{17} which is not included in the uncertainties listed in the following tables. Our reproduction of these known resonances assures us that our simulations correctly incorporate the detector response.

![FIG. 2: Levels of interest in the 1p decay of $^{11}$N states, 2p decay of $^{12}$O states, and their analogs in $^{12}$N. Green arrows show $\gamma$-ray decays of importance, while observed 1p decays are shown as the straight blue arrows. The dashed curves show possible sequential decay paths of $^{12}$O states investigated in this work. The curved blue arrows indicate direct 2p decay. The 0$_2^+$ $^{12}$O state from 20 is also shown. For the decay of $^{12}$N levels, only isospin-allowed intermediate and final states are shown.](image)

### IV. IN Variant-Mass Spectra

Invariant-mass spectra for all the isotopes examined in this work are presented in this section. The level schemes of Fig. 2 contain new and previously known levels, and can be used to aid in understanding the discussions.

#### A. $^{11}$N structure

The structure of $^{11}$N is important for $^{12}$O decay as its levels are possible intermediate states in sequential 2p decays. The $E_T$ spectrum from detected $p^{+10}$C events is shown as the black histogram in Fig. 3(a). From this spectrum we have subtracted two types of contaminations. First, a small fraction of $^{11}$C fragments leak into the $^{10}$C gate. To estimate the spectrum from such events, we have taken the detected $p^{+11}$C events and analyzed the $^{11}$C fragment as $^{10}$C. This spectrum is scaled by the probability of misidentification determined from the calibration beams ($\sim0.5\%$) to give the red histogram in Fig. 3(a). Its magnitude is only significant at very small values of $E_T$. Secondly, $^{12}$O→$2p^{+10}$C events in which one of the protons was not detected will also contribute to the detected $p^{+10}$C events. To account for this, we have taken the detected $2p^{+10}$C events and randomly thrown away one of the protons, scaling the separate $p^{+11}$C invariant-mass spectra (blue histogram) based on the results of the Monte-Carlo simulation to appropriately represent the number of contaminated events from this process.

The contamination-subtracted spectrum is shown as the data points in Fig. 3(b) and largely represents the yield from the knockout of both a proton and a neutron.
mass spectrum with 5 levels (6 peaks), including the known states indicated by the black arrows and one new level. \( R \)-matrix line shapes are used for all levels except for the new states where a simple Breit-Wigner shape is assumed, as the decay orbital angular momentum is unknown. The energies and widths of the unresolved 1/2\(^+\) and 5/2\(^+\) states were fixed to the ENSDF values, but their presence allows for a good fit with a smooth background (blue dashed curve). The fitted branching ratio of the 3/2\(^-\) state is \( \Gamma_{p_0}/(\Gamma_{p_0} + \Gamma_{p_1}) = 0.64(6) \). Fitted energies and widths are listed in Table III. The new \( E_T = 2.563\) MeV state, can correspond to either a 1.073-MeV or 4.416-MeV level depending on whether the proton decay is to the ground or first excited state of \(^{10}\text{C}\). No known mirror states in \(^{11}\text{Be}\) exist for the lower possibility, but a couple of candidate exist for the higher value, suggesting that the decay is to the \(^{10}\text{C}\) excited state.

### B. \(^{12}\text{O}\) Structure

#### 1. 2\(p\)+\(^{10}\text{C}\) channel

The \( E_T \) spectrum for the 2\(p\)-decay of \(^{12}\text{O}\) is shown in both Figs. (1c) and (d). There are four peak structures present in the spectrum. The spin assignments of the three prominent peaks come from an analysis of the mirror, \(^{12}\text{Be}\), presented in [22], the predictions of [13, 23, 24], and previous work [7]. The low-energy shoulder on the 2\(^+\) peak [Fig. (1c)] is at the approximate location of the second \(0^+\), \( E^* = 1.62(13) \) state measured in [20]. It is also at the approximate energy for the \(1^-\) state predicted with GCC calculations (\( E_T = 3.256 \) MeV) [13]. Alternatively, this structure may be a second \(2p\) decay branch of the 2\(^+\) excited state to the \( E^* = 3.353\) MeV, \( J^\pi = 2^+\), particle-bound first excited state as the shoulder is located \( \sim 3.353 \) MeV lower in \( E_T \) than the ground state decay.

The data were fitted with Monte-Carlo simulations using Breit-Wigner intrinsic line shapes that incorporated the detector response. The numerics, extracted decay energies, widths, and cross sections of each state are given in Table III. The decay width of the shoulder state is

\(^b\) Based on our new value for the ground-state energy.

\(^c\) Parameters fixed to ENSDF values in fit.
subject to a large uncertainty, as demonstrated by the fit with different background parameterizations in Figs. 1(c) and 1(d). The extracted centroid and width are consistent with the values of $E^* = 1.62(13)$ and $\Gamma = 1.2$ MeV for the 0$^+_2$ state from $^{20}$O. On the other hand, if the shoulder peak is a decay branch of the second 2$^+$, we can fix its decay energy and width and refit the spectrum [Fig. 6(a)], obtaining a branching ratio for this component of 0.27(1).

This paper presents the first observation of a second 2$^+$ state, which was predicted to be produced in $^{13}$O knockout reactions in 23. Note that the analysis of 23 predicts four 2$^+$ states, though only two are expected to have significant strength (the first and fourth) and the fourth (presumably our 2$^+_2$ state) should have four times the yield of the 2$^+_1$ state, which is not observed.

2. 4p+2α channel

Figure 4(a) displays the reconstructed total-decay-energy spectrum of detected 4p+2α events which shows a peak sitting atop a large background. Assuming a single level with a Breit-Wigner line shape, the fitted spectrum is shown as the solid curve with fitted parameters: $E_T = 7.972(40)$ MeV, $\Gamma = 0.81(11)$ MeV.

With the large multiplicity of exit-channel fragments, it is not easy to disentangle how this state decays, especially as it sits on a large background. Among the possible decay scenarios there are sequential decay pathways which are initiated by an $\alpha$+$^{16}$C/$^6$Be+$^9$Be split or 2p decay to higher-lying excited states of $^{10}$C. In all these scenarios, sequential decays of the unstable decay products lead to the observed exit channel.

Of the possible intermediate states, $^8$Be$_{g.s.}$ is cleanest to isolate as there is only one possible $\alpha$-$\alpha$ subevent in each 4p+2α event and the $\alpha$-$\alpha$ invariant-mass peak has no background under it. The invariant-mass spectrum gated and vetoed by the presence of a $^8$Be intermediate state is shown in Fig. 4(b). Peaks are present in both spectra, indicating there are at least two decay pathways, but, as we will see, there are many more.

Other possible intermediate states can be identified using various combinations of the decay fragments. For instance, the invariant-mass spectra of 4p+α subevents is shown in Fig. 4(c). Note there are two ways to make 4p+α subevents for each 4p+2α event. This spectrum shows the presence of a peak from the decay of $^8$Be$_{g.s.}$ at $E_T = 3.449$ MeV 23. On the other hand, for $^{10}$C intermediate states, the combinatorics give us 6 2p+α subevents for each event. Rather than dealing with all these subevents, the invariant-mass spectrum in Fig. 4(d) used only 2p+2α subevents where one of the $p+2\alpha$ subevents has an invariant mass corresponding to $^9$Be$_{g.s.}$ decay. This spectrum shows the presence of a prominent peak at $E_T = 1.45$ MeV corresponding to the 5.18-MeV state of $^{10}$C which is known to sequentially proton decay through $^9$Be$_{g.s.}$ to $^8$Be$_{g.s.}$ 21. Finally there are also 6 ways to separate a detected event into two subgroups of 2p+α events from which one can search for the fission of $^{12}$O into two $^6$Be fragments. Plotting the decay energies of the prospective $^6$Be fragments against each other produces the 2D plot shown in Fig. 4(a). A sharp peak for which the two $^6$Be fragments are in their ground states can be discerned ($E_T = 1.37$ MeV). To make this more obvious, we have employed the diagonal gate shown by the dotted lines and projected onto either one of the axes to produce the spectrum shown in Fig. 4(b). Apart from g.s.+$g.s.$, peak there is a broad peak at ~3.5 MeV somewhat above the expected energy if both $^6$Be fragments are in the $E^*_T = 1.16$ MeV, $J^* = 2^+$ state. Its origin is not clear.

By subtracting a smooth background under all the peaks in Fig. 4 a multiplicity for each observed intermediate resonance and a probability for the $^6$Be$_{g.s.+}^6$Be$_{g.s.}$ channel can be determined. These various multiplicities are plotted against $E_T$ in Fig. 4(c). In addition to the resonances discussed, multiplicities were also determined for the occurrence of a single $^6$Be$_{g.s.}$ and for the $J^* = 5/2^-$, $E^*_T = 2.345$-MeV of $^9$B. These multiplicities are inclusive and so for example the $^8$Be$_{g.s.}$ yield from the decay of $^9$Be$_{g.s.}$ is included in the $^8$Be$_{g.s.}$ multiplicity. The $E_T$

$^b$Assuming the shoulder peak is a decay branch of the second 2$^+$.
$^c$Through the 4$^p$+2$\alpha$ decay channel.

bin centered around the observed peak is marked by the fatter data points near 8 MeV. If these intermediate resonances are associated mainly with the $^{12}$O peak and not with the large background under it, then the multiplicities should have a maximum at the $E_T$ value for the peak ($E_T^{peak}$). This is clearly not the case. On the other hand, if the intermediate resonances come purely from the background, then the multiplicities should have a minimum at $E_T^{peak}$. According to our fit in Fig. 4(a), the peak to background yield for the $E_T$ bin centered on the peak is $\sim$1:1. Thus we would expect a suppression of 50% at the peak $E_T$ relative to the trend from the other $E_T$ bins in this scenario. Again this is also not the case. Thus we conclude that all these intermediate resonances are found in both the peak and the background beneath it with similar magnitudes. Making a more quantitative statement is impossible as the overall trend is non-linear and thus difficult to determine if the peak multiplicities are slightly larger or smaller than the overall trend.

We conclude that about 50% of the events in the observed $^{12}$O peak decay by producing at least one $^6$Be$_{g.s.}$ and another $\sim$20% have a $^9$Be$_{g.s.}$ fragment. The latter is responsible for most of the observed $^6$Be$_{g.s.}$ yield. The fission-like channels $^6$Be$_{g.s.}$+$^6$Be$_{g.s.}$ and $\alpha$+$^8$C$_{g.s.}$ are responsible for $\sim$9% and $\sim$6% of the yield, respectively. The above analysis may miss wider intermediate states which are more difficult to discern above the backgrounds.

C. $^{12}$N structure

1. 2$\alpha$+$^{10}$B channel

Known low-lying $^{12}$N states were observed in the $p+$11C spectrum in Fig. 1(b). Higher-lying excited states can be found in the 2$p+$10B spectrum in Fig. 6(b). This spectrum bears a strong resemblance to the 2$p+$10C spectrum which is also reproduced in panel (a) for convenience. Both spectra contain three prominent peaks with the same energy spacing between them. In addition, the second of these peaks in both cases has a low-energy shoulder. This surprising result suggests that all the
peaks in the 2p+10B spectrum are analogs of the observed 12O levels. Indeed, the lowest-energy peak was also observed in the invariant-mass study of Jager et al. [7] and it was argued that it was produced by the prompt 2p decay of the Isobaric Analog State (IAS) of 12O in 12N to the IAS in 10B. The latter subsequently γ decays. This represented a second example of prompt 2p decay from one IAS to another 23. The other example is the IAS of 8C in 7B which 2p decays to the IAS state in 6Li where the γ ray from the decay of 6LiIAS was observed 24. In both cases, prompt 2p decay was the only particle-decay mode which conserved both energy and isospin.

If these other states are also analog states (T=2), then the two higher-energy states are both Jπ=2+ and also involve 2p decay to the IAS of 10B. The low-energy shoulder on the lowest 2+ peak can again have contributions from three possible sources, i.e., from T=2, Jπ=0+ or 1− levels or from a decay branch of a higher-energy 2+ state which decays to the first T=1, Jπ=2+ state in 10B (Fig. 4). The red solid curve in Fig. 6(b) shows a fit obtained with Breit-Wigner intrinsic line shapes where the third origin of the low-energy shoulder is assumed. Figure 6(a) shows a similar fit to the 2p+10C decay channel of 12O, assuming the shoulder state decays to the excited state of 10C. For the decay of 12N, the known energy of the first T=1, Jπ=2+ 10B state is used to constrain its Eγ centroid relative to the fitted value for the second 2+ state. The fitted branching ratio is 0.087(12) which is smaller than the corresponding value obtained for the 12O→2p+10C shoulder state (see Sec. IV B 1).

Although the 2p+10B and 2p+10C spectra in Fig. 6 have similar structure, the obvious difference is the much smaller relative yield for the 12NIAS peak (Eγ∗=10.502) compared to that for the other peaks. The cross sections for the 2+ particles in 12N are about ~50% of the corresponding 12O levels. Based on this scaling, we expect the yield of 0+ 12N IAS to be a factor of ~3 larger than observed. The simplest explanation would be that 12NIAS has one or more other decay branches which account for most of the decay leaving the 2p branch with only ~30% of the yield. If these other branches involve particle emission, then they must violate isospin symmetry, but no candidate peaks were observed in other 11N exit-channels. We cannot rule-out other particle-decay branches as some of these will have very low detection efficiency, e.g., single-proton decay to the 11Cg.s. where the emitted proton will mostly travel to angles outside the detectors angular acceptance. Another possibility is that the 12NIAS has a significant M1 γ decay strength to the ground state which would satisfy the spin and isospin selection rules.

2. 2p+α+6Li channel

While the analogs of the low-lying 12O levels have been found, we have also searched for the analog of the higher-lying 12O level observed in the 4p+2α channel. Given the large number of decay paths inferred for this state, it is reasonable to assume multiple exit-channels associated with the analog state, some of which would contain neutrons and not accessible with the experimental apparatus. However, the analog of the fission-like 6BeB, +6BeB, +α+6B, channels in 12O would be 6BeB, +6LiIAS and α+8BIAS which would populate the 2p+α+6Li+γ exit channel. No peaks are observed in the raw 2p+α+6Li invariant-mass spectrum, but with suitable gating the analogs can be found. The invariant-mass spectra from the 2p+α and 2p+6Li subevents are shown in Fig. 7(a) and 7(b), respectively.

The peak observed in the 2p+6Li exit channel [Fig. 7(b)] is consistent in energy and width to a peak observed following proton knockout from a 9C beam 9. It was identified as a 8BIAS →2p+6LiIAS decay where the γ ray from the decay of 6LiIAS was observed in a subsequent experiment. Gating on the 8BIAS peak produces the 2p+α+6Li invariant-mass spectrum in Fig. 7(d). Taking into account the energy of the unobserved gamma ray (3.563 MeV), the excitation energy of the 12N→α+8BIAS state is at 21.970(66) MeV.

A 6Be ground-state peak is observed in the invariant-mass spectrum for the 2p+α subevents [Fig. 7(a)]. Gating on this peak produces the invariant-mass spectrum in Fig. 7(c). In principle this peak could correspond to either a 6BeB, +6LiB, or 6BeB, +6LiIAS decay. However, the fitted Eγ∗ values and widths of the peaks in

$^a$Includes contribution from the shoulder state.

3. $3p+^{9}\text{Be}$ channel

As the $^{12}\text{O} \rightarrow 4p+2\alpha$ peak appears to have a significant probability of decaying to $^{9}\text{Be}_{g.s.}$ intermediate states, its analog in $^{12}\text{N}$ could decay to the $3p+^{9}\text{Be}$ exit channel. The invariant-mass spectrum for these events is shown in Fig. 7(b) and displays a well resolved peak at an excitation energy consistent with that inferred for the $^{12}\text{N} \rightarrow 2p+\alpha+^{6}\text{Li}$ peaks. See Table IV for comparison of peak parameters from Breit-Wigner fits. However the fitted intrinsic width of this state is considerably smaller than the $(T=2)$ $2p+\alpha+^{6}\text{Li}$ peaks, indicating that it must be associated with a different $^{12}\text{N}$ level. It may even be a $T=1$ state. However we suspect it is a $T=2$ state, and if this is true, it implies that the observed peak in the analog spectrum, $^{12}\text{O} \rightarrow 4p+2\alpha$, is not a singlet.

Further information on the decay of this state can be gleaned from the invariant-mass spectrum of the $p+^{9}\text{Be}$ subevents in Fig. 8(a). A prominent peak at $E^* \sim 7.47$ MeV is observed which could be one or both of the $E^*=7.470$-MeV ($J^\pi=2^+$, $T=0$) and $E^*=7.479$-MeV ($J^\pi=2^-$, $T=1$) excited states of $^{10}\text{B}$. The multiplicity of this peak is plotted as a function of $^{12}\text{N}$ excitation energy in Fig. 8(a). The smooth green dashed curve was fitted to excitation-energy bins beyond the peak region and suggests that there might be a small enhancement of this intermediate state at the peak energy. However, this curve is not well constrained for energies below the peak value. Nevertheless, it is clear that this intermediate-state peak is associated with a significant fraction of the $^{12}\text{N} \rightarrow 3p+^{9}\text{Be}$ peak yield. If the $^{12}\text{N}$ state is $T=2$ as suspected, then the intermediate state must be the $T=1$, $J^\pi=2^-$ state. We also see a suggestion of some smaller yield for the $T=1$, $J^\pi=3^-$ ($E^*=8.887$ MeV) and $2^+$ ($E^*=8.895$ MeV) $^{10}\text{B}$ states in the $p+^{9}\text{Be}$ spectrum in Fig. 8(c), but it is difficult to extract multiplicities as the relative magnitude of the background is much larger.

FIG. 7: Data obtained for $2p+\alpha+^{6}\text{Li}$ coincidences. The upper panels show (a) $2p+\alpha$ and (b) $2p+^{6}\text{Li}$ invariant-mass spectra for these subevents. No $\cos \theta_c$ gate was applied. (c,d) show invariant-mass spectra obtained from the $2p+\alpha+^{6}\text{Li}$ events gated on the $^{6}\text{Be}_{g.s.}$ and $^{8}\text{Be}_{IAS}$ invariant-mass peaks in (a) and (b), respectively. The curves in (c,d) are fits assuming a single Breit-Wigner lineshape.

Figs. 7(c) and 7(d) (given in Table IV) are consistent, suggesting that they are decay branches of the same state. Thus the peak in Fig. 7(c) corresponds to the fission-like $^{6}\text{Be}_{g.s.}+^{6}\text{Li}_{IAS}$ decay.
V. DISCUSSION

A. Analog States

To further explore the analog states in $^{12}$O and $^{12}$N, we have looked at their consistency with the other $A=12$ quintet states. Figure 9 plots the level scheme of the newly found levels relative to the energy of the lowest $T=2, J^*=0^+$ state. In addition, $T=2$ levels for $^{12}$B [27] and $^{12}$Be [21] are included. There is excellent consistency for the energy of the first $T=2 J^*=2^+$ state. The second such $2^+$ state in $^{12}$Be is not known, but a state at $E^*=4.580$ MeV has been assigned as either $2^+$ or $3^-$ [21]. This state is at the right energy to be the mirror of the $2^+$ state in $^{12}$O and thus leads us to strongly favor the $2^+$ assignment.

The masses in an isospin multiplet are expected to follow the isospin multiplet mass equation (IMME),

$$\Delta M = a + bT_z + cT_z^2,$$

if isospin is a good quantum number [29]. The largest deviations from this behavior have been found for $A=8$ and $A=9$ [25, 29, 30]. Deviations from the IMME for $A=12$ quintet were previously examined in [7], but with our newer, more accurate measurement for $^{12}$O and $^{12}$N it is worth examining again. The mass excess for the quintets associated with the $0^+$ and first second $2^+ T=2$ states are plotted in Fig. 10(a). Results for $^{12}$C were taken from [21] and for the second $2^+$ state of $^{12}$Be, we have included the candidate state previously mentioned. The curves show fits with the quadratic IMME which can reproduce the data validating our assumption that the $^{12}$N states are $T=2$.

Figure 10(b) shows deviations from the quadratic form for the two lower-energy quintets. The error bars on some of the points for the $2^+$ states are too large to look for meaningful deviations from the IMME. In the case of the $0^+$ states, if we include a cubic term ($dT_z^3$) to Eq. (3), then we find $d = 1.6(37)$ keV consistent with zero and small compared to values of $d = 8.36(21)$ keV for the $A=8$ quintet and $d = 6.33(16)$ keV for the $A = 9$ quartet [31]. There is thus no evidence for deviations from the quadratic IMME for the $A=12$ quintet.

The fission-like channels $^6$Be$_{g.s.} + ^6$Be$_{g.s.}$, $^6$Be$_{g.s.} + ^6$Li$_{J=4}^{16}$, $^\alpha + ^8$C$_{g.s.}$, and $^\alpha + ^8$B$_{J=4}$ remind us of the $^6$He$^+ ^6$He and $^\alpha + ^8$He decay channels for levels in $^{12}$Be observed in [32, 33] and which were associated with a molecular $\alpha-2\alpha$ band structure [32]. The lowest member of this band was subsequently found at $E^* = 10.3$ MeV [33, 34] and shown to be $J^*=0^+$. The location of this level is plotted in Fig. 9 for comparison. While its excitation energy would be appropriate for an analog to the fission-like states we observed in $^{12}$O and $^{12}$N, its quoted width of $\Gamma = 1.5(2)$ MeV is too large to be consistent as more neutron-rich analogs are closer to stability and thus should have smaller widths. In any case these fission-like decay modes suggest these states have strong cluster structure.
and one of the protons ($E_x = E_{pp\text{-core}}$). In the Jacobi-Y case, $\cos \theta_k \sim 1$ corresponds to a small relative angle between the momenta of the two protons. The Jacobi 2D plots for $^{12}\text{O}_{g.s.}$ are compared to those obtained for ground-state emission of $^{6}\text{Be}$ and $^{16}\text{Ne}$ in Fig. 11.

All these data were obtained with the same detector setup, and approximately the same beam $E/A$ value, so the effect of the detector resolution and efficiency will be similar. All channels display features that are expected for $2p$ decay, including suppressions due to the Coulomb interaction when one of the protons and the core have the same velocity vectors (e.g. $E_x/E_T \sim 0.56$, $\cos \theta_k = \pm 1$ in the Jacobi T plots) and when the two protons have the same velocity vectors (e.g. $E_x/E_T \sim 0.5$, $\cos \theta_k = -1$ in the Jacobi Y plots). It is also clear that the two protons are emitted with approximately the same kinetic energy, as the ridges in the Jacobi Y distribution are centered near $E_x/E_T \sim 0.5$.

The $^{12}\text{O}$ results are remarkably similar to those for $^{16}\text{Ne}_{g.s.}$, and both differ from the $^{6}\text{Be}$ results having relatively more yield for diproton-like decays, i.e., small $E_x/E_T$ in the Jacobi T plots or negative $\cos \theta_k$ values in the Jacobi Y plots. Further comparison can be made with the projections of the distributions on their energy axis which are shown in Fig. 12 as the histograms. The similarity of the $^{12}\text{O}_{g.s.}$ and $^{16}\text{Ne}_{g.s.}$ data are confirmed in these projections. This similarity was predicted by Grigorenko et al. in their 3-body calculations [2].

In addition to the ground-state emitters, we have also included projections for the $2p$ decays of $^{12}\text{N}_{\text{IAS}}$ and $^{8}\text{B}_{\text{IAS}}$ as the data points. We note all the correlation data can be subdivided into two groups with similar projections: the first group - lighter $p$-shell systems $^{6}\text{Be}_{g.s.}$ and $^{8}\text{B}_{\text{IAS}}$ - and the second group - the heavier $^{12}\text{O}_{g.s.}$, $^{12}\text{N}_{\text{IAS}}$, and $^{16}\text{Ne}_{g.s.}$ systems. The $^{8}\text{B}_{\text{IAS}}$ $2p$ decay may be considered a surrogate for the first step of the decay of its analog, i.e., $^{8}\text{C}_{g.s.} \rightarrow 2p + ^{6}\text{Be}_{g.s.} \rightarrow 4p + \alpha$ [22]. One should also note the similarity of the correlations for $^{12}\text{N}_{\text{IAS}}$ to its analog $^{12}\text{O}_{g.s.}$ reinforcing this notion. The degree of similarity is probably helped by the fact that $E_T$ is very similar for all systems (Table IV), as the three body-model of Grigorenko et al. indicates that there is a $E_T$ dependence of these projections [36, 37].

The similarity for all the heavier systems is expected as they all have significant $|s_{1/2}^20\rangle$ components in their wavefunction and this component dominates the decay. On the other hand, $^{6}\text{Be}_{g.s.}$ is dominated by the $|p_{3/2}^20\rangle$ component, but there is some mixing with $|s_{1/2}^20\rangle$ under the barrier [36, 37] and the final distribution is a mixture of $|p_{3/2}^20\rangle$ and $|s_{1/2}^20\rangle$ components. The similarity between the projections for $^{6}\text{Be}_{g.s.}$ and $^{8}\text{B}_{\text{IAS}}$ ($^6\text{C}_{g.s.}$) is quite interesting. The interior wavefunction of the valence protons can contain $p_{1/2}^2$ and $p_{3/2}^2$ components. The emission of a $p_{1/2}^2$ pair of protons would be expected to yield correlations more like the heavier systems as $|p_{1/2}^20\rangle$ emission is expected to have a similar phase space as $|s_{1/2}^20\rangle$ [38]. It is possible that the $^{8}\text{B}_{\text{IAS}}$ result is telling us that the wavefunction is dominated by the $p_{3/2}^2$
FIG. 11: Experimental momentum correlation plots for the ground-state 2p decays of $^6$Be, $^{12}$O, and $^{16}$Ne. Results are shown in both the Jacobi T (upper panels) and Jacobi Y (lower panels) representations. The $^{12}$O data is from this work while the $^6$Be and $^{16}$Ne data are from Refs. [4, 5].

TABLE V: Decay energies for prompt 2p emitters in Fig. 12.

| Nucleus | $E_T$ [MeV] | Ref. |
|---------|-------------|------|
| $^6$Be  | 1.372       | [41] |
| $^8$B$_{IAS}$ | 1.313   | [41] |
| $^{12}$O$_{g.s.}$ | 1.688(29) | this work |
| $^{12}$N$_{IAS}$ | 1.165(29) | this work |
| $^{16}$Ne$_{g.s.}$ | 1.466(20) | [5] |

component as predicted in the complex scaling model [39]. However, other models predict the addition of more complex configurations in the mirror nucleus [40]. Calculations of the correlations for this system would help us better understand the structure of $^8$C, but the systematics of the presented correlations for light 2p emission demonstrate that they contain structural information for the parent state.

Figure 13 shows the Jacobi Y momentum correlations for $E_T$ bins centered on the three prominent peaks ($0^+_1$, $2^+_1$, and $2^+_2$) in the $2p+^{10}$C invariant-mass spectra in Fig. 1(c). The $2^+_1$ bin contains contributions from the shoulder state and the $2^+_2$ bin contains a background contribution. Examination of the neighboring region to these peaks suggest these contributions have similar correlations. The correlations evolve from the prompt 2p decay for the ground state [Fig. 13(a)] to a sequential-like decay for the $2^+_2$ state which displays two vertical ridges [Fig. 13(c)]. The latter decay is more complicated than the classical notion of sequential as we will see, but is it useful to determine which $^{11}$N intermediate state these ridges are consistent with.
FIG. 13: Jacobi Y momentum correlations for $E_T$ bins centered on (a) $0^+_1$, (b) $2^+_1$, and (c) $2^+_2$ states. The $2^+_1$ results in (b) contained contributions from the shoulder state. The energy gates for the spectra are $1.43 < E_T < 2.02$ MeV for (a), $3.45 < E_T < 4.04$ MeV for (a), and $5.85 < E_T < 6.06$ MeV for (c).

Figure 14 compares the experimental $2^+_1$ correlations to simulations of sequential decay via the $R$-matrix formalism [42] through the $1/2^-$ [panel (c)] first-excited state and the $3/2^-$ [panel (d)] fourth-excited state of $^{11}$N. Both simulations produced ridges in similar locations to the experimental data. In these simulations, one ridge is vertical, corresponding to the second emitted proton whose relative energy with the core is independent of angle, and a sloping ridge, corresponding to the first emitted proton whose relative energy to the core depends of the recoil imparted by the second proton and thus dependent on $\cos \theta_k$. In the experimental data, the differentiation of the ridges into a vertical and sloping varieties is not obvious. It is possible that both $^{11}$N intermediate states are involved and wash out this differentiation. For example, the correlations plot in Fig. 14(b) was obtained from incoherently adding the two decay paths with equal weight. If we have contribution from the $3/2^-$ $^{11}$N intermediate state, then as this state has a decay branch to the excited state of $^{10}$C (Sec. IV A), this will contribute yield in the “shoulder state” (Sec. IV A).

While there are sequential aspects of the $2^+_1$ correlations in Fig. 13(c), the yield along the ridges changes rapidly with $\cos \theta_k$ decreasing as $\cos \theta_k \to 1$. If there is no memory between the two decay steps, one expects a distribution symmetric about $\cos \theta_k=0$, even if there is interference between the two proposed decay paths as the two intermediate states have the same parity. Figure 14 shows the projection of the Jacobi Y distribution, corrected for the detection efficiency, as the square data points. To reduce the background contribution, the data have been selected with a narrow gate (1.4-MeV wide) at the peak of the $2^+_1$ state. To estimate the remaining background, we placed a gate between the two intermediate states have the same parity. Figure 14 shows the projection of the Jacobi Y distribution, corrected for the detection efficiency, as the square data points. To reduce the background contribution, the data have been selected with a narrow gate (1.4-MeV wide) at the peak of the $2^+_1$ state. To estimate the remaining background, we placed a gate between the two intermediate states have the same parity. Figure 14 shows the projection of the Jacobi Y distribution, corrected for the detection efficiency, as the square data points. To reduce the background contribution, the data have been selected with a narrow gate (1.4-MeV wide) at the peak of the $2^+_1$ state. To estimate the remaining background, we placed a gate between the two intermediate states have the same parity. Figure 14 shows the projection of the Jacobi Y distribution, corrected for the detection efficiency, as the square data points. To reduce the background contribution, the data have been selected with a narrow gate (1.4-MeV wide) at the peak of the $2^+_1$ state. in the 3-body model as an interference between sequential and prompt decay components. The sequential decay of the $^{17}\text{Ne}$ second excited state also shows a preference for small $\theta_{pp}$ after the proton-proton final state interaction was considered, but the magnitude was much smaller than observed here \[44\]. In the $^{17}\text{Ne}$ case, the $^{16}\text{F}$ intermediate state had a much smaller decay width ($\Gamma \sim 20$ keV) than the two possible $^{11}\text{N}$ intermediate states we determined for the decay of the $2^+_2$ state. This suggests that this memory effect diminishes as the time between the two sequential decays increases.

The correlations in Fig. 15(b) for the $2^+_2$ state are dominated by a banana-shaped structure in the diproton region ($\cos \theta_k < 0.5$). A look at the upper half of the correlation plot reveals the presence of two clear ridges suggesting a sequential-like decay component. As mentioned before, the sloping ridge corresponds to the emission of the first proton. The sloping ridge is the one on the right in Fig. 15(b), so this proton has more energy than the second one. As the decay scheme in Fig. 2 shows, the only level that the $2^+_1$ state can decay through to give the correct energy ordering is the $1/2^+$ ground state of $^{11}\text{N}$. These ridges are further investigated by the energy-projection of Fig. 15(b) for $\cos \theta_k > 0.5$ that is plotted as the data points in Fig. 16.

The resonance energy and width of $^{11}\text{N}_{g.s}$ is not well-defined as seen by the discrepancy of level parameters from three studies \[13, 45, 46\] given in Table VII. These values were used in the ENDF evaluation \[21\]. By examining the sequential-component, it might be possible to clear up some of the confusion about the decay parameters of this state. The curves plotted in Fig. 16 show sequential predictions obtained with the different parameter sets from these three studies. The experimental data does not appear to agree with a decay through the $^{11}\text{N}_{g.s}$ as described by \[45\]. It is also difficult to claim agreement with either \[13\] or \[46\], as the experimental peaks appear to lie directly between the two curves. Our data would suggest an intermediate resonance energy to those from \[45, 47\]. We provide our own fit to the data in Fig. 16(b) which gives a decay energy of 1.378(5) MeV and a width of 0.78(1) MeV. A smooth background (dot-dashed curve) was added to enable the reproduction of the wings of the experimental distribution.

### C. Comparison to GCC predictions

The structure of $^{12}\text{O}$ states have recently been predicted with the Gamow coupled-channel approach \[13\] which treats $^{12}\text{O}$ as two protons interacting with a deformed $^{10}\text{C}$ core. The wavefunction of the protons is expanded using the Berggren basis, which includes bound and scattering states, thus considering the effect of the continuum. An initial comparison with the experimental levels of $^{12}\text{O}$ was made in \[13\] and the predicted ground-state width was found to be similar to the experimental value. It is interesting to see if the sequential-decay components of the observed $2^+_2$ states are consistent with the predicted internal structure. The wavefunction com-

FIG. 15: Efficiency-corrected projection of the Jacobi Y correlation plot for the $2^+_2$ $^{12}\text{O}$ state on the $\cos \theta_k$ axis. Results are shown for (square data points) for a tight gate on the invariant-mass peak and for background gates on either side of this peak (triangles and open circles). An axis showing the relative angle $\theta_{pp}$ between the protons is also included.
components predicted for the three $2^+$ states are listed in Table [VI].

The $2^+_1$ state has a sequential component which decays through the $J^\pi=1/2^+$ ground state of $^{11}$N, consistent with the sequential removal of a $d$ and then an $s$ wave proton. This matches well with the largest component of the predicted wavefunction for this state. This component and the next largest component ($d_{5/2}, d_{3/2}$) could also produce a sequential decay contribution through the $5/2^+$ state in $^{11}$N (See Fig. [2]), but as the decay energy of the first proton would be small, the barrier penetration fraction appears to have suppressed it.

Our second observed $2^+$ state at $E_T=6.5$ MeV is similar in energy to both the GCC predictions for the second and third $2^+$ state. The two proposed sequential components deduced from the correlation plot both involve the emission of two $p$-wave protons and thus suggest that our observed $2^+_2$ level is also the second $2^+$ state in the calculations, which is dominated by a ($p_{1/2}, p_{3/2}$) structure. Indeed the two sequential decay paths can then be interpreted as differing in the order in which the $p_{1/2}$ and $p_{3/2}$ proton are emitted.

VI. CONCLUSIONS

Levels in $^{11}$N, $^{12}$N, and $^{12}$O have been observed with the invariant-mass technique using single- and multiple-nucleon knockout reactions from a $^{13}$O beam at $E/A=69.5$ MeV. The charged-particle decay products produced from interactions with a $^9$Be target were detected with the HiRA array. The $J^\pi=1/2^-_1$ and $3/2^-_1$ levels were observed in the $^{11}$N→$p^{10}$C invariant-mass spectra and the $3/2^-$ state was deduced to have decay branches to the ground and first excited states in $^{10}$C. In addition a new state was observed in this channel at either $E^\pi=1.073(10)$ or $4.416(10)$ MeV.

High-statistics spectra were obtained for the 2$p$ decay of $^{12}$O in which a second $2^+$ state was observed for the first time. The $2^+_1$ peak in this spectrum was found to have a low-energy shoulder which could have contributions from the $0^+_1, 1^-_1$, or a second $2^+$ decay branch of the $2^+_1$ state to the excited state in $^{10}$C. A higher-lying $^{12}$O state was observed in the $4p+2\alpha$ exit channel which has contributions from a number of different decay paths including fission-like decays, i.e. $\alpha+^{8}C_{g.s.}$ and $^6$Be$_{g.s.}+^{6}$Be$_{g.s.}$.

Analogs to these $^{12}$O states were also observed in $^{12}$N. The $2p+^{10}$B invariant-mass spectrum was very similar to that for $^{12}$O→$2p+^{10}$C with the same peak structure. These peaks were shown to arise from $2p$ decay of $T=2$ states to the isobaric analog state in $^{10}$B. Higher-lying $T=2$ states were also observed in the $2p+\alpha+^{6}$Li spectrum corresponding to fission-like decay to $\alpha+^{8}B_{IAS}$ and $^6$Be$_{g.s.}+^{6}$Li$_{IAS}$. An additional $^{12}$N peak was found at the same excitation in the $3p+^{9}$Be channels that probably is also $T=2$, but results from the decay of a separate level.

The momentum correlations in the prompt $2p$ decay of $^{12}$O$_{g.s.}$ were found to be almost identical to those measured previously in $^{16}$Ne$_{g.s.}$ consistent with prediction of the 3-body model of Grigorenko et al. [2]. These correlations were also found to be rather consistent with those for the $2p$ decay of its isobaric analog state in $^{12}$N. The correlations for the $2^+_3$ state of $^{12}$O show evidence of sequential decay through the $3/2^+_1$ and/or the $1/2^-_1$ intermediate states in $^{11}$N. However, the distribution of relative angles between the protons was strongly biased to small angles, qualitatively consistent with the results for the second excited states of $^{16}$Ne [13]. This may be a general feature of sequential decay through wide intermediate states.

The correlations for the $2^+_1$ state show the presence of a significant diproton-like component, but a sequential-decay component through the ground-state of $^{11}$N is also observed. The latter component allowed for a new determination of the $^{11}$N$_{g.s.}$ Decay through this intermediate state is consistent with the internal structure at the $2^+_1$ level in $^{12}$O predicted with Gamow coupled-channels calculations. No deviation from the quadratic isobaric multiplet mass equation was found for the $A=12$ quintet.
