(Dated: December 30, 2013)

In this work, we theoretically construct exact mappings of many-particle bosonic systems onto quantum rotor models. In particular, we analyze the rotor representation of spinor Bose-Einstein condensates. In a previous work [1] it was shown that there is an exact mapping of a spin-one condensate of fixed particle number with quadratic Zeeman interaction onto a quantum rotor model. Since the rotor model has an unbounded spectrum from above, it has many more eigenstates than the original bosonic model. Here we show that for each subset of states with fixed spin $F_z$, the physical rotor eigenstates are always those with lowest energy. We classify three distinct physical limits of the rotor model: the Rabi, Josephson, and Fock regimes. The last regime corresponds to a fragmented condensate and is thus not captured by the Bogoliubov theory. We next consider the semiclassical limit of the rotor problem and make connections with the quantum wave functions through use of the Husimi distribution function. Finally, we describe how to extend the analysis to higher-spin systems and derive a rotor model for the spin-two condensate. Theoretical details of the rotor mapping are also provided here.

I. INTRODUCTION

The behavior of macroscopic systems of multicomponent bosons under suitable constraints can often be greatly simplified through a quantum rotor description. Within the context of condensed matter physics, the most widely appreciated example is the celebrated Josephson model [2–3]. This model provides an accurate low-energy treatment of two superconductors linked by an insulating barrier [4]. The treatment of the full many-particle system reduces to a model with two canonically conjugate variables: the relative particle number and phase between the two superconducting regions.

Bose-Einstein Condensates composed of atoms with internal spin or pseudospin degrees of freedom, the so-called spinor condensates, offer another arena where such rotor mappings are highly useful. Roughly speaking, recent experimental work investigating the dynamics of spinor condensates can be divided into two categories. The first category of experiments focuses on the complex interplay between spatial and spin degrees of freedom resulting from spinor condensates in larger traps [5–10]. These experiments investigate the dynamics after a quantum quench, which involves the proliferation of topological defects. The second category of experiments are performed in tight traps where the spatial degrees of freedom are unimportant [11–19]. Such experiments have focused on the coherent spin dynamics after preparing the system in a particular manner. The rotor description is useful when the spatial degrees of the condensate can be neglected, and thus is particularly relevant to the second class of experiments.

In an early theoretical work on spinor condensates it was shown that the ground state of the antiferromagnetic condensate in tight traps involves large spin correlations and can be considered to be a condensate of singlet pairs of spin-one atoms [20]. However, such “fragmented” states [21, 22] are known to be extremely del-
two operators in this equation are canonically conjugate:

\[ [\alpha, \beta] = i. \]  

The spectrum of the Josephson model can be seen to agree with the original double-well model Eq. (1) in the large-particle number limit.

In the work of Anglin et al. [32], it was shown that such a mapping can be made exact, and thus will reproduce the spectrum of Eq. (1) for arbitrary particle number. Their derivation used a method akin to the Bargmann phase-space representation of bosonic operators [39]. Here we will derive their central result through a different method. To start, we define the states

\[ \langle \Omega_N | = \frac{1}{\sqrt{2^N N!}} \left( a_1^\dagger e^{i\theta} + a_2^\dagger e^{-i\theta} \right)^N | 0 \rangle \]  

\[ = \frac{1}{\sqrt{N!}} \left( \Omega \cdot b^\dagger \right)^N | 0 \rangle \]  

where \( \Omega = (\cos(\theta), \sin(\theta)) \) is a real two-component vector on the unit circle and the “Cartesian” bosonic operators \( b_x \) and \( b_y \) are defined to be \( b_x = \frac{1}{\sqrt{2}} (a_1 + a_2) \), \( b_y = \frac{1}{\sqrt{2}} (a_1 - a_2) \). These states can be shown to form an overcomplete basis. For instance, the fragmented state \( (a_1^\dagger)^{N/2} (a_2^\dagger)^{N/2} | 0 \rangle \) can be seen to be an equal weight superposition of these states over the unit circle [22]. Therefore, an arbitrary state \( |\Psi\rangle \) in the bosonic Hilbert space can be expressed in terms of a superposition over the states \( |\Omega_N \rangle \) with weight factor \( \psi(\Omega) \)

\[ |\Psi\rangle = \int d\Omega \langle \Omega_N | \psi(\Omega) \rangle. \]  

Note that due to the overcompleteness, this relation does not uniquely determine \( \psi(\Omega) \). The approach of the mapping is to find a Hamiltonian \( H \) acting in the “rotor” space such that

\[ \int d\Omega \langle \Omega_N | (H |\Omega_N \rangle \psi(\Omega) \rangle = \int d\Omega \langle \Omega_N | (H \psi(\Omega)) \rangle. \]  

Then the rotor Schrodinger equation \( H\psi = i\hbar \partial_t \psi \) is a sufficient condition for the bosonic Schrodinger equation to be satisfied (we will work in units where \( \hbar = 1 \) unless otherwise stated).

In obtaining \( H \), we use the gradient operator \( \nabla \) on the unit circle, which in terms of \( \theta \) is \( \nabla_x = -\sin(\theta) \partial_{\theta} \) and \( \nabla_y = \cos(\theta) \partial_{\theta} \). These derivatives satisfy the geometrically intuitive relations

\[ \nabla_x \Omega_\beta = \delta_{\alpha \beta} - \Omega_\alpha \Omega_\beta \]  

(for a discussion see Appendix A). With this, it can be seen that quadratic operators acting on \( |\Omega_N \rangle \) can be written as

\[ b_\alpha^\dagger b_\beta |\Omega_N \rangle = \Omega_\beta (\nabla_\alpha + N \Omega_\alpha) |\Omega_N \rangle \]  

In terms of the Cartesian operators, the double-well Hamiltonian (up to a constant offset) is

\[ H = -J (b_x^\dagger b_x - b_y^\dagger b_y) + \frac{U}{4} (ib_x^\dagger b_y - ib_y^\dagger b_x)^2. \]
We can now use the relation in Eq. (8) to find
\begin{equation}
(b_x^2 - b_y^2)|\Omega_N\rangle = (N \cos(2\theta) - \sin(2\theta)\partial_\theta)|\Omega_N\rangle
\end{equation}
and
\begin{equation}
(i b_x^2 b_y - i b_y^2 b_x)|\Omega_N\rangle = L_{xy}^2|\Omega_N\rangle
\end{equation}
where \(L_{xy} = -i\Omega_x\nabla_y + i\Omega_y\nabla_x = -i\partial_\theta\). The effective rotor Hamiltonian can then be obtained by inserting these relations into Eq. (9), and integrating by parts. One finds
\begin{equation}
\mathcal{H} = \frac{1}{4}Un^2 - J(N + 2)\cos(2\theta) - iJ\sin(2\theta)n
\end{equation}
where \(n = i\partial_\theta\). While the operator \(\mathcal{H}\) has a real spectrum it is not Hermitian due to its last term. However, one can apply a similarity transform to render \(\mathcal{H}\) Hermitian. Specifically, defining 32
\begin{equation}
\mathcal{H}' = e^{\cos(2\theta)\hat{J}}\mathcal{H}e^{-\cos(2\theta)\hat{J}}
\end{equation}
and shifting \(\theta \to \theta/2\) to compare with Eq. (2) one finds
\begin{equation}
\mathcal{H}' = Un^2 - J(N + 1)\cos(\theta) + \frac{J^2}{U}\sin^2(\theta)
\end{equation}
which is the main result. Note that this reduces to Eq. (2) in the large-\(N\) limit. The additional terms in Eq. (2), however, serve to make the spectrum of the original double-well Hamiltonian Eq. (1) exactly match the eigenstates of this rotor model.

III. SPIN-ONE CONDENSATES IN THE SINGLE-MODE REGIME

We now move on to discuss the related, but more complex, problem of the spinor condensate in the single mode regime under an external magnetic field. Recently it was shown 1 that this system maps onto a quantum rotor model under an external magnetic field. Here we will summarize this mapping.

Our starting point is a spin-one condensate in a trap that is sufficiently tight such that it is a good approximation to take all of the bosons to occupy the same spatial mode. Under this approximation, we can write the field operators for each spin state as
\begin{equation}
\psi_\alpha(r) = \phi(r)a_\alpha
\end{equation}
where \(\alpha\) runs from \(-1\) to 1. The condensate profile satisfies
\begin{equation}
\int d^3r |\phi(r)|^2 = N
\end{equation}
where \(N\) is the number of particles in the system. This approximation, commonly referred to as the single mode approximation, breaks down when the condensate coherence length is larger than the condensate size.

The Hamiltonian for this system reads
\begin{equation}
H = \frac{g}{2N}F^2 - qa_0^*a_0.
\end{equation}
In this equation, \(F = a_\alpha^*F_\alpha\beta a_\beta\) is the total spin operator where \(F_{\alpha\beta}\) is spin-one matrices, \(g\) is the spin-dependent interaction, and \(q\) is the quadratic Zeeman shift due to an external magnetic field. Taking a uniform condensate density \(\phi(r) = \sqrt{n_0}\), we can express \(g\) in terms of microscopic parameters as
\begin{equation}
g = \frac{4\pi\hbar^2}{3m}(\bar{a}_2 - \bar{a}_0)n_0
\end{equation}
where \(m\) is the mass of the constituent atoms, and \(\bar{a}_0\) and \(\bar{a}_2\) are the scattering lengths. We will focus on the case of antiferromagnetic interactions for which \(g > 0\) as is the case for \(^{23}\text{Na}\) condensates.

As was done for the double-well problem in Sec. II it is useful to transform the bosonic operators to the Cartesian basis, rewriting the operators as \(b_x = -(a_1 - a_{-1})/\sqrt{2},\quad b_y = (a_1 + a_{-1})/i\sqrt{2},\) and \(b_z = \theta_0\). Written in terms of these, the spin operator becomes \(\mathbf{F} = -i\mathbf{b} \times \mathbf{b}\).

We next define the overcomplete set of states as
\begin{equation}
|\Omega_N\rangle = \frac{1}{\sqrt{N!}}(\Omega \cdot \mathbf{b})^N|0\rangle
\end{equation}
which are parametrized by a three-component vector on the unit sphere \(\Omega\) (note that the analogous states in Sec. II were parameterized on the unit circle).

The general mapping proceeds with the general method given above in Sec. II. Namely, one writes a general bosonic wave function as a superposition of states in the \(|\Omega_N\rangle\) basis, and finds an operator \(\mathcal{H}\) acting in the rotor Hilbert space which satisfies Eq. (6) (where the integration is generalized to the unit sphere). The full derivation is given in Ref. 11 and thus we will only give the results here. The rotor Hamiltonian corresponding to Eq. (17) is
\begin{equation}
\mathcal{H} = \frac{g}{2N}L^2 - q(N + 3)\Omega^2 + q\Omega_z\nabla_z
\end{equation}
where \(L_\alpha\) is the angular momentum operator and \(\nabla_\alpha\) are the gradient operators on the unit sphere. In the spherical coordinate representation, \(\nabla_z = -\sin(\theta)\partial_\theta\). This can be brought to the more intuitive Hermitian form by applying a similarity transformation. In particular, defining \(\mathcal{H}' = e^{-S}\mathcal{H}e^S\) where \(S = \frac{2N}{49}\cos(2\theta)\), we find
\begin{equation}
\mathcal{H}' = \frac{1}{2I}L^2 + V(\theta)
\end{equation}
where \(I = N/g\) is the moment of inertia, and
\begin{equation}
V(\theta) = q\left(N + \frac{3}{2}\right)\sin^2(\theta) + \frac{g^2N}{8g}\sin^2(2\theta)
\end{equation}
is the external potential. The spectrum of this Hamiltonian exactly matches that of Eq. (17). As was described in 11 one must retain only the eigenstates of
IV. CORRESPONDENCE OF THE ROTOR AND BOSONIC EIGENVALUES

There are subtleties that arise due to the fact that the rotor model Eq. (21) has an unbounded spectrum from above, while the spectrum of the original bosonic problem for fixed particle number $N$ if finite. As is clear from the mapping, an eigenstate of the rotor model $ψ$ is a sufficient condition for an eigenstate of the bosonic Hamiltonian $|Ψ\rangle$. That is, given $ψ$, one can construct the bosonic eigenstate through

$$|Ψ\rangle = \int dΩ(ΩN)ψ(Ω). \quad (23)$$

Here for simplicity we are taking $ψ$ to be an eigenstates of the non-Hermitian rotor model $H$ so that we do not need to include factors of $e^{iS}$. Because the spectrum of the bosonic Hamiltonian $H$ is bounded, the only possibility is that many of the rotor eigenstates get transformed to $|Ψ\rangle = 0$ through Eq. (23), noting that this trivially satisfies the bosonic Schrodinger equation. Following Ref. 32 we will refer to the rotor eigenstates which transform to $|Ψ\rangle \neq 0$ as “physical” and those that transform to $|Ψ\rangle = 0$ as “unphysical”.

We next ask if all of the eigenstates of the bosonic spectrum are included in the rotor description. For instance, the pathological case of all the rotor eigenstates mapping to $|Ψ\rangle = 0$ is not a priori ruled out. Another question that arises regards the ordering of the unphysical and physical eigenstates. In particular, is there an energy cutoff below which all eigenstates are physical and above which eigenstates are unphysical? We will show that there is an affirmative answer to both of these questions.

For sufficiently small particle number $N$, the eigenspectrum of the bosonic Hamiltonian Eq. (17) can be numerically computed and compared to the eigenspectrum of the rotor system Eq. (21). The rotor Hamiltonian has azimuthal symmetry since the potential $V$ appearing in Eq. (22) does not depend on the angle $φ$. Therefore, $H$ commutes with $L_z$ and the eigenspectrum for fixed values $L_z = m$ can be considered separately. Similarly, $F_z$ commutes with the bosonic Hamiltonian $H$, and we can compare to the rotor model by fixing $F_z = -m$. In Fig. 1 the eigenspectrum of both the rotor model and the bosonic model are shown as a function of the quadratic Zeeman field $q$. We take the case of relatively small particle number $N = 20$, and take fixed $F_z = L_z = 0$. As can be seen, all of the eigenenergies of the bosonic Hamiltonian are accounted for by the rotor model. Furthermore, the physical states of the rotor model are always lower in energy than the unphysical states. Similar behavior was found for other values of fixed $L_z = m \neq 0$ which are not shown.

This behavior can be understood as follows. For unphysical states $ψ(Ω)$, it can be seen from Eq. (23) that $⟨Y_ℓm|ψ⟩ = 0$ for all $ℓ \leq N$. It can be verified that the (non-Hermitian) rotor Hamiltonian defined in Eq. (20) has the property

$$⟨Y_ℓm|H|Y_ℓm'⟩ = 0 \quad (24)$$

for $ℓ \leq N$ and $ℓ' > N$. Suppose that we have a rotor eigenstate which is unphysical for parameters $(q, g)$. Then the eigenstate at $(q + Δq, g)$ can be determined by first order perturbation theory. By doing so, one sees from Eq. (24) that if a state is unphysical at $q$ then the same state will also be unphysical at $q + Δq$. In the limit of $q = 0$, the rotor model becomes trivial. Here the eigenstates are simply spherical harmonics with eigenenergies $E_ℓ = ℓ(ℓ + 1)$. Furthermore, the lowest eigenstates for $ℓ \leq N$ are all physical while the higher eigenstates for $ℓ > N$ are unphysical in this limit. We note that for fixed $L_z = m$, the rotor Hamiltonian becomes one dimensional. Thus there will not be any band crossings 40. From the perturbative argument above, we therefore conclude that the higher energy states will always
remain unphysical and not mix with the lower energy physical states.

V. EIGENSPECTRA OF THE ROTOR MODEL

In this Section we will concentrate on the eigenspectrum of the spin-one rotor hamiltonian given in Eq. (21). We will give the spectrum in particular limiting cases, and compare the results with those the Bose-Hubbard Dimer problem.

We consider how the spectrum evolves as a function of \( q \). For large \( q \), the potential energy \( V(\theta) \) in Eq. (22) serves to localize the wave function on the unit sphere. To obtain the energy levels, the angular momentum \( L^2 \) can be expanded about the north pole so that \( H \) becomes a two-dimensional harmonic oscillator. When \( 1 \ll q/g \), the second term in the potential energy \( V(\theta) \) dominates so that the energy levels are given by

\[
E_{(n_x, n_y)} = q(n_x + n_y) \tag{25}
\]

where \( n_x \) and \( n_y \) are integers corresponding to the oscillator modes in the \( x \) and \( y \) directions. These eigenstates can in fact be directly obtained from the original bosonic hamiltonian Eq. (17) in the large-\( q \) limit.

Next we consider the case of smaller \( q \) where \( 1/N^2 \ll q/g \ll 1 \). For this case, the first term in the potential energy is the most significant. Here we can also expand the kinetic energy about the north pole to obtain a harmonic oscillator hamiltonian. For this the energy levels read

\[
E_{(n_x, n_y)} = \sqrt{2q(n_x + n_y)} \tag{26}
\]

where, as in Eq. (25), \( n_x \) and \( n_y \) are integers. As shown in Appendix C it can be seen that the Bogoliubov spectrum of Eq. (17) agrees with Eqns. (25, 26).

Finally we consider the case of vanishingly small magnetic field such that \( q/g \ll 1/N \). For this case the eigenfunctions are not localized about the north pole. The kinetic energy \( \frac{1}{27} L^2 \) dominates the rotor model and the eigenstates are given simply by

\[
E_\ell = \frac{g}{2N}(\ell + 1). \tag{27}
\]

Each of these energy levels has multiplicity \( 2\ell + 1 \). So that the wave function has inversion symmetry, only even values of \( \ell \) should be kept. The ground state in this regime where the rotor is completely delocalized about the unit sphere, in terms of the bosonic model, is the fragmented condensate composed of singlet pairs of bosons. However, due to the condition \( q/g \ll 1/N^2 \), in the thermodynamic limit any small magnetic field will drive the system to a symmetry broken state which is described well by mean field theory \cite{23, 25}. This is the central difficulty in experimentally realizing the singlet condensate. We will address this problem in more detail in Appendix D.

It is instructive to compare the above results with the dimer Bose-Hubbard model. This model has been analyzed and found to have three distinct limits, namely the “Rabi”, “Josephson”, and “Fock” regimes using the terminology of Leggett \cite{37, 41}. Using a method very similar to that used above, the expressions for the energy eigenstates can be obtained in these regimes from the rotor Hamiltonian in Eq. (14). Namely, for the Rabi regime where \( N \ll J/U \) the last term in the potential energy dominates and the spectrum is approximated by a harmonic oscillator, after expanding about \( \theta = 0 \). The Josephson regime occurs when the first term in the potential energy dominates \( 1/N \ll J/U \ll N \). Here the states are also localized about \( \theta = 0 \). Finally, for \( J/U \ll 1/N \) the Fock regime is obtained where the rotor is delocalized over the unit circle. The Josephson Hamiltonian Eq. \( 2 \) correctly describes the Fock and Josephson regimes, but cannot describe the Rabi regime since a large-\( N \) expansion is used to derive it. In summary, the three possible regimes for the dimer Bose-Hubbard model are

\[
N \ll J/U : \text{Rabi} \quad \tag{28}
\]
\[
1/N \ll J/U \ll N : \text{Josephson} \quad \tag{29}
\]
\[
J/U \ll 1/N : \text{Fock}. \quad \tag{30}
\]

It is clear that there is a close parallel between the above described regimes for the dimer Bose-Hubbard model and those of the spin-one condensate problem. For this reason we will adopt the terminology introduced in \cite{27, 41} for the spinor problem. Namely, we will label the three regimes as

\[
1 \ll q/g : \text{Rabi} \quad \tag{31}
\]
\[
1/N^2 \ll q/g \ll 1 : \text{Josephson} \quad \tag{32}
\]
\[
q/g \ll 1/N^2 : \text{Fock}. \quad \tag{33}
\]

For typical experimental situations (for example those describe in Refs. \cite{18, 19}) \( q \sim g \) and \( N \sim 10^3 - 10^5 \) which places the system in either the Rabi or Josephson regimes. For these cases, the Gross-Pitaevskii equation gives a qualitatively correct description of the dynamics.

It is also interesting to note that for double-well condensates the Rabi regime is more difficult to achieve since by reducing the hopping \( J \) to achieve the condition in Eq. (28), a single-band description becomes inapplicable. On the other hand, the Fock regime for double-well condensates can be experimentally achieved, which has the Mott Insulating ground state \cite{22, 43}.

VI. SEMICLASSICAL ANALYSIS OF THE ROTOR MODEL

In this Section we analyze the semiclassical limit of the rotor model in Eq. (21). We will use this to address recent experimental results. We will then show results from taking the Husimi transform of the quantum eigenstates of the rotor model. Such a method has been shown
to elucidate the semiclassical limit of the Bose-Hubbard dimer model [34].

In recent experiments [18, 19] the dynamics of a $^{23}$Na condensate, which has antiferromagnetic interactions $g > 0$, was investigated. The initial condensate was prepared in a fully polarized ferromagnetic state pointing in the $x$ direction after which the condensate was allowed to freely evolve. The value of $\langle F_x \rangle^2$ was measured as a function of time. Two distinct types of behavior were found, depending on the external magnetic field which couples to the system through the quadratic Zeeman shift $q$. A separatrix between these two behaviors occurs at a critical magnetic field $B_c$. When $B < B_c$, $\langle F_x \rangle^2 > 0$ at all times. On the other hand, when $B > B_c$ it was seen that $\langle F_x \rangle^2 = 0$ at periodic intervals during its evolution. An analysis of the behavior was provided in terms of the classical Gross-Pitaevskii energy functional. Taking into account the conserved quantities (total particle number and spin moment in the $z$-direction which was fixed to be $\langle F_z \rangle = 0$), the two-dimensional phase portrait of the energy functional was shown to capture these two regimes.

We will now describe how the semiclassical limit of Eq. (21) gives an intuitive understanding of these results. The corresponding Lagrangian is

$$\mathcal{L} = \frac{1}{2} I \left( \dot{\theta}^2 + \sin^2(\theta) \dot{\phi}^2 \right) - V(\theta),$$

where $V(\theta)$ is given by Eq. (22). This gives the canonical momenta $p_\theta = I \dot{\theta}$ and $p_\phi = I \sin^2(\theta) \dot{\phi}$. The corresponding classical energy is

$$E = \frac{1}{2I} \left( p_\theta^2 + \frac{p_\phi^2}{\sin^2(\theta)} \right) + V(\theta).$$

The above equations describe the motion of a particle on a unit sphere. We will concentrate on the case where $p_\phi = 0$. The classical equal-energy contours of Eq. (35) are plotted in the left panel of Fig. 2. Two types of behavior are seen. The higher-energy states have motion where the particle’s trajectory explores both hemispheres but has either $p_\theta > 0$ or $p_\theta < 0$ at all times thus never having zero angular momentum. This corresponds to the motion of the spin-one condensate for $B < B_c$. Increasing the magnetic field will constrain the particle’s trajectory to one hemisphere. For this motion, it is seen that $p_\theta = 0$ at periodic intervals during the particle’s trajectory. This type of motion corresponds to $B > B_c$ of the spin-one condensate experiment [44].

We will now move on to discuss the semiclassical properties manifest in the quantum mechanical wave functions of Eq. (21) for appropriate parameter regimes. To do this, we will use a generalization of the Husimi distribution function [33] to the case of the sphere. The Husimi distribution function has been successfully applied to elucidate the pendulum structure manifest in the

FIG. 2. Left: Equal-energy contours of the semiclassical energy given in Eq. (35) for $p_\phi = 0$. Right: Husimi distribution functions $H(\mathbf{r})$ for particular eigenstates of the rotor model Eq. (21) for the parameters $q = g$, $N = 10$, and $\kappa = 1/10$. Panels (b), (c), (d), (e) respectively correspond to the 2nd, 4th, 6th, and 8th excited states within the manifold of $m = 0$ and even $\ell$. The classical equal-energy contours corresponding to the energies of the states plotted on the right are shown in red. The same range of $p_\theta$ and $\theta$ is used for all plots.
wave functions of double-well condensates described by Eq. (1).

Conventionally, the Husimi distribution function of a particular wave function $|\psi\rangle$ is defined as

$$H(z) = \frac{|\langle z|\psi\rangle|^2}{\langle z|z\rangle}$$

(36)

where $|z\rangle$ is a scaled coherent state. For our considerations, we thus need a generalization of the notion of a coherent state to the unit sphere. Recent work on such a generalization is given in Refs. [45, 46]. In [45] it was argued that it is most natural to define spherical coherent states to be eigenstates of the “annihilation” operators

$$A_\alpha = e^{-\frac{1}{2}\kappa L^2} \Omega_\alpha e^{\frac{1}{2}\kappa L^2}$$

(37)

where $\kappa$ is a scaling parameter [47]. Such eigenstates are given by

$$|z\rangle = \sum_{\ell m} e^{-\kappa(\ell+1)/2} |Y_{\ell m}\rangle Y_{\ell m}^*(z).$$

(38)

In this equation $z$ is a three-component complex vector that satisfies $z \cdot z = 1$. In terms of classical phase space variables $(p = p_\theta + p\phi \phi)$ and $\Omega$, $z$ can be expressed as

$$z = \cosh(\kappa p)\Omega + \frac{i}{p} \sinh(\kappa p)p.$$  

(39)

The value of the scaling parameter should be taken such that $\kappa^2 \sim \frac{2}{7N\gamma}$ which is the ratio of the prefactors of the kinetic and potential energies in Eq. (21).

We consider the case where $q = q$ and $N = 10$ bosons which places the system between the Josephson and Rabi regimes, and well away from the Fock regime. Density plots of the Husimi distribution function for particular rotor eigenstates are shown in the right of Fig. 2. Since we concentrate on the case of $F_z = 0$, the Husimi distribution function will only depend on the pair of variables $(\theta, p_\theta)$. Red classical equal-energy contours shown on the right of Fig. 2 are drawn for energies corresponding to these eigenstates. One sees that the Husimi distribution functions strongly resemble the semiclassical contours, thus revealing the semiclassical behavior of the eigenstates. Such agreement occurs for all states in the Rabi and Josephson regimes, but not for the Fock regime which has no semiclassical correspondence.

VII. EXTENSION TO HIGHER SPINS

We will now move on to discuss how to perform the rotor mapping for larger spin systems. We will focus on $F = 2$ spinor condensates because of their experimental availability as hyperfine states of alkali atoms. We will show that this system maps to a particle moving on a sphere in five-dimensional space.

Spin-two condensates have five spin components. We take $a_\alpha$ for $\alpha = -2 \ldots 2$ to annihilate a boson with $F_z = \alpha$. In the single-mode regime, spin-two condensates are described by the Hamiltonian

$$H = \frac{g_1}{2N} F^2 + \frac{g_2}{2N} A^4 A.$$  

(40)

Here, $F = a_\alpha^\dagger F_{\alpha\beta} a_{\beta}$ is the total spin operator where $F_{\alpha\beta}$ are spin-two matrices. In the second term, $A = a_0a_0 - 2a_1a_{-1} + 2a_1a_{-1}$ annihilates a singlet pair of bosons. In terms of physical quantities, the coefficients $g_1, 2$ are given by

$$g_1 = \frac{4\pi \hbar^2}{\ell_m} n_0(\bar{a}_4 - \bar{a}_2)$$

(41)

$$g_2 = \frac{4\pi \hbar^2}{m} n_0 \left[ \frac{1}{2} (\bar{a}_0 - \bar{a}_4) - \frac{2}{7} (\bar{a}_2 - \bar{a}_4) \right]$$

(42)

where $\bar{a}_0, \bar{a}_2,$ and $\bar{a}_4$ are the spin-two s-wave scattering lengths. For simplicity we will neglect the effects of an external magnetic field on this system.

We perform the following unitary transformation on the bosonic operators:

$$b_1 = a_0$$

(43)

$$b_2 = \frac{1}{\sqrt{2}} (-a_{-1} - a_1)$$

(44)

$$b_3 = \frac{1}{\sqrt{2}} (a_{-1} - a_1)$$

(45)

$$b_4 = \frac{1}{\sqrt{2}} (a_2 - a_{-2})$$

(46)

$$b_5 = \frac{1}{\sqrt{2}} (a_2 + a_{-2}).$$

(47)

These operators transform as a vector under SO(5) rotations generated by $M_{\alpha\beta} = -i[b_{\alpha}^\dagger b_{\beta} - b_{\beta}^\dagger b_{\alpha}]$. In terms of these quantities, the singlet operator is

$$A = b \cdot b$$

(48)

while the spin operators are

$$F_x = \sqrt{3} M_{12} - M_{25} + M_{34}$$

(49)

$$F_y = \sqrt{3} M_{13} + M_{24} + M_{35}$$

(50)

$$F_z = M_{23} + 2M_{45}.$$  

(51)

As before, we can parametrize an overcomplete set of states (but now using the five-component, real unit vector $\Omega$) as

$$|\Omega_N\rangle = \frac{1}{\sqrt{N!}} \left( \sum_{\alpha=1}^{5} \Omega_\alpha b_\alpha^\dagger \right) |0\rangle.$$  

(52)

The mapping proceeds along similar lines to that in Secs. III and IV. In particular, one finds that

$$M_{\alpha\beta} \rightarrow -L_{\alpha\beta}.$$  

(53)
where \( L_{\alpha \beta} = -i(\Omega_\alpha \nabla_\beta - \Omega_\beta \nabla_\alpha) \). This can be used to find the rotor correspondence of the first term in Eq. 40.

Next we find the rotor correspondence of the second term in Eq. 40. We use the five-component version of Eq. 8 to find that

\[
A^\dagger A|\Omega_N\rangle = (\nabla^2 + N^2 + 3N)|\Omega_N\rangle. \tag{54}
\]

In this equation, \( \nabla^2 \) is the Laplacian on the five-dimensional hypersphere, as described in Appendix A. The integration-by-parts here is straightforward. One obtains

\[
A^\dagger A \rightarrow \nabla^2 + N^2 + 3N. \tag{55}
\]

The resulting rotor model, which is already Hermitian, is thus

\[
\mathcal{H} = \frac{g_2}{2N} \nabla^2 + \frac{g_1}{2N} \left( (\sqrt{3}L_{12} - L_{25} + L_{34})^2 + (\sqrt{3}L_{13} + L_{24} + L_{35})^2 + (L_{23} + 2L_{45})^2 \right) \tag{56}
\]

where we have dropped a constant energy offset. This model has a particularly simple form in the limit of \( g_1 = 0 \). Here the system has an SO(5) symmetry, and the ground state will be a condensate of singlet pairs of spin-two bosons.

VIII. CONCLUSION

In this work we have analyzed in detail rotor mappings of spinor condensates in the single mode regime. We have addressed some subtleties related to the physical and unphysical eigenstates and showed that the rotor mapping gives an exact treatment of the spinor condensate. Since the rotor model treats the mean field as well as correlated phases on equal footing it offers new insights into the problem. We have established both the importance of the rotor model in providing physical insight into the properties of spinor condensates and its validity as a practical scheme for carrying out calculations.

There are several interesting directions that can be pursued in future work. The Husimi distribution function has proven useful for understanding the collapse and revival process of atoms in the proximity of a superfluid-insulating phase transition. Such a phase-space analysis of the collapse and revival dynamics for the spinor system close to the Fock regime will prove to be valuable. We emphasize that for this regime the semiclassical correspondence illustrated in Fig. 2 will not hold.

In Sec. VII we derived the rotor representation of the spin-two system for a single site. The mean-field phase diagram of the spin-two condensates is known to have a degeneracy for nematic states which is lifted by quantum and thermal fluctuations. A generalization Eq. 56 to include quadratic Zeeman field will prove useful for studying this effect for smaller condensates where quantum effects are more pronounced. Finally, we note that low energy effective rotor theories of spinor condensates (without magnetic fields) where previously investigated in [52, 53]. It will be interesting to investigate how the rotor mapping generalizes to include spatial degrees of freedom.

ACKNOWLEDGMENTS

It is our pleasure to acknowledge useful discussions with A. Lamacraft, P. Lett, and W. Reinhardt. This work was supported by the NSF Joint Quantum Institute Physics Frontier Center. We thank the hospitality of the Kavli Institute of Theoretical Physics under the grant NSF PHY05-51164 where part of this work was completed.

Appendix A: Quantum mechanics on the hypersphere

In this Appendix, for convenience, we will tabulate the properties of a particle constrained to the surface of a \( d \)-dimensional hypersphere. The position of the particle is given by \( d \) coordinates \( \Omega_\alpha \) (for \( \alpha = 1, \ldots, d \)) subject to the constraint \( \Omega \cdot \Omega = 1 \). The momentum operators are \( \pi_\alpha = -i\nabla_\alpha \) where \( \nabla_\alpha \) is the gradient operator in the \( \alpha \)-direction on the hypersphere (which can be expressed in terms of \( d - 1 \) angles and their derivatives). Finally, the angular momentum operators are \( L_{\alpha \beta} = \Omega_\alpha \pi_\beta - \Omega_\beta \pi_\alpha \). Note that for \( d = 3 \), the angular momentum is conventionally written with a single subscript as \( L_\alpha = \frac{1}{2} \epsilon_{\alpha \beta \gamma} L_{\beta \gamma} \). The position and angular momentum are Hermitian operators, while the Hermitian conjugate of \( \pi_\alpha \) is

\[
\pi_\alpha^\dagger = \pi_\alpha + i(d - 1)\Omega_\alpha \tag{A1}
\]

The following commutation relations are satisfied for the position and momentum operators:

\[
\begin{align*}
[\Omega_\alpha, \Omega_\beta] &= 0 \tag{A2} \\
[\Omega_\alpha, \pi_\beta] &= i(\delta_{\alpha \beta} - \Omega_\alpha \Omega_\beta) \tag{A3} \\
[\pi_\alpha, \pi_\beta] &= -iL_{\alpha \beta}. \tag{A4}
\end{align*}
\]

These can be seen to give the angular momentum operators the correct commutation relations which are \( [L_{\alpha \beta}, L_{\gamma \delta}] = i\delta_{\alpha \gamma}L_{\beta \delta} + i\delta_{\beta \delta}L_{\alpha \gamma} - i\delta_{\alpha \delta}L_{\beta \gamma} - i\delta_{\beta \gamma}L_{\alpha \delta} \). These operators satisfy the orthogonality relation \( \Omega \cdot \pi = 0 \) (i.e. the momentum and position are orthogonal on the hypersphere). It can also be verified that the total angular momentum can be expressed as

\[
\frac{1}{2} \sum_{\alpha \beta} L_{\alpha \beta} L_{\beta \alpha} = \pi \cdot \pi = -\nabla^2. \tag{A5}
\]

Appendix B: Rotor model with general coupling

In this Appendix we consider spin-one Hamiltonians with more general coupling to external fields. In particu-
ular, we consider Hamiltonians of the form
\[ H = \frac{g}{2N} F^2 + b_\alpha^\dagger B_{\alpha\beta} b_{\beta}. \]  
where \( B \) is a Hermitian matrix. One can see that this reduces to Eq. (17) for the special case \( B_{\alpha\beta} = -gq_{\alpha\kappa} \delta_{\beta\zeta}. \) In the following it is useful to write \( B \) in terms of its real and imaginary parts as \( B = B' + iB'' \). Since \( B \) is Hermitian, we have the requirement that \( B' \) is symmetric while \( B'' \) is antisymmetric.

Applying the rotor mapping as in Sec. III one arrives at the non-Hermitian Hamiltonian
\[ \mathcal{H} = \frac{g}{2N} L^2 + q(N + 3)B_{\alpha\beta} \Omega_{\alpha} \Omega_{\beta} - B_{\alpha\beta} \Omega_{\beta} \nabla_{\alpha} \]  
which should be compared to Eq. (20). To bring this Hamiltonian to Hermitian form we apply the similarity transformation \( \mathcal{H} = e^{-S} \mathcal{H} e^S \) where
\[ S = \Gamma_{\alpha\beta} \Omega_{\alpha} \Omega_{\beta} \]  
where \( \Gamma \) is a matrix. One can verify that by choosing \( \Gamma = \frac{N}{2g} B' \), provided \( B' \) and \( B'' \) commute, \( \mathcal{H} \) becomes Hermitian. In particular, for this value of \( \Gamma \),
\[ \mathcal{H} = \frac{1}{2l} L^2 + V(\theta, \phi) \]  
where
\[ V(\theta, \phi) = \left( N + \frac{3}{2} \right) \Omega^T B' \Omega + \frac{1}{2} B''^T L_{\beta\alpha} \]  
\[ + \frac{N}{2g} (\Omega^T B'^2 \Omega - (\Omega^T B' \Omega)^2) . \]  
One can check that this reduces to Eq. (21) in the appropriate limit.

**Appendix C: The Bogoliubov spectrum of Eq. (17)**

It is instructive to compute the low lying spectrum of the spinor Hamiltonian Eq. (17) through the Bogoliubov method [55] and compare with the results from the exact rotor mapping given in Sec. V. We expand about classical mean-field state given by \( \hat{a}_1 = \hat{a}_{-1} = 0 \) and \( \hat{a}_0 = \sqrt{N} \), and write the bosonic operators as \( a_\alpha = \hat{a}_\alpha + \delta a_\alpha \). The constraint of fixed particle number \( N \) can be enforced up to quadratic order by requiring
\[ -\sqrt{N}(\delta a_0 + \delta a_0^\dagger) = \delta a_1^\dagger \delta a_1 + \delta a_{-1}^\dagger \delta a_{-1}. \]  
Dropping constant terms, Eq. (17) becomes up to quadratic order
\[ H = (g + q)(\delta a_1^\dagger \delta a_1 + \delta a_{-1}^\dagger \delta a_{-1}) + g(\delta a_1 \delta a_{-1} + \text{h.c.}). \]  
It is straightforward to diagonalize this by a Bogoliubov transformation. The result is
\[ H = \sqrt{q(2g + q)}(\alpha^\dagger \alpha + \beta^\dagger \beta) \]  
where \( \alpha \) and \( \beta \) are bosonic annihilation operators which is consistent with [50]. The spectrum of this Hamiltonian can be seen to agree with the results derived from the rotor model in Sec. V in the Rabi regime, Eq. (25), and Josephson regime, Eq. (26). However, the results do not agree in the Fock regime, Eq. (27), since the Bogoliubov treatment is inapplicable for a fragmented condensate.

**Appendix D: Experimental realization of the singlet condensate**

In this Appendix, we will discuss the experimental parameters necessary to achieve the singlet condensate. In the Josephson regime, the ground state wave function of the rotor model is
\[ \psi(\theta) = \sqrt{\frac{2}{\pi \theta^2}} e^{-\theta^2/\bar{\theta}^2} \]  
where \( \theta = \sqrt{\frac{2g}{N}} \). As can be verified from (32), in the Josephson regime, \( \bar{\theta} \ll 1 \). Decreasing the magnetic field and thereby decreasing \( g \), one sees that the width of the wave function increases. When the width of the wave function \( \bar{\theta} \) approaches unity, the harmonic description of the condensate fails and the Fock regime is entered [33]. As mentioned earlier, in the limiting case of \( q = 0 \) the ground state is a condensate of singlet pairs of spin one bosons.

We thus ask what parameters are necessary for \( \bar{\theta} \sim 1 \). Because this quantity scales inversely with the number of particles, this state cannot be achieved in the thermodynamic limit. We therefore concentrate on systems with relatively small particle number. For the \(^{23}\text{Na}\) system, the parameters \( g \) and \( q \) appearing in the rotor model Eq. (21) are related to the atomic density and external magnetic field \( B \) through [18]
\[ g = (1.59 \times 10^{-52} \text{Jm}^3) n_0 \]  
\[ q = (1.84 \times 10^{-35} \text{J}/(\mu \text{T})^2) B^2. \]

For a fixed particle number, increasing the density increases \( \bar{\theta} \). We thus take \( n_0 = 5 \times 10^{14} \text{cm}^{-3} \), which is relatively large, but still small enough that three-body losses are not important. Then for small magnetic field \( B = 0.1 \mu \text{T} \) and \( N = 500 \) particles, we have \( \bar{\theta} = 1.9 \) which is outside of the Josephson regime. If quenched from finite magnetic field, such a system will exhibit quantum collapse and revival oscillations [1].
