Abstract. Cadmium–Zinc–Telluride Imager (CZTI) onboard AstroSat has been a prolific Gamma-Ray Burst (GRB) monitor. While the 2-pixel Compton scattered events (100–300 keV) are used to extract sensitive spectroscopic information, the inclusion of the low-gain pixels (~20% of the detector plane) after careful calibration extends the energy range of Compton energy spectra to 600 keV. The new feature also allows single-pixel spectroscopy of the GRBs to the sub-MeV range which is otherwise limited to 150 keV. We also introduced a new noise rejection algorithm in the analysis ('Compton noise'). These new additions not only enhances the spectroscopic sensitivity of CZTI, but the sub-MeV spectroscopy will also allow proper characterization of the GRBs not detected by Fermi. This article describes the methodology of single, Compton event and veto spectroscopy in 100–900 keV combined for the GRBs detected in the first year of operation. CZTI in last five years has detected ~20 bright GRBs. The new methodologies, when applied on the spectral analysis for this large sample of GRBs, has the potential to improve the results significantly and help in better understanding the prompt emission mechanism.

Keywords. AstroSat—CZT imager—sub-MeV spectroscopy—gamma ray burst.

1. Introduction

Cadmium–Zinc–Telluride Imager (hereafter CZTI) on board AstroSat (Singh et al. 2014; Paul 2013), India’s first dedicated astronomical satellite, has been demonstrated as a prolific Gamma Ray Burst (GRB) monitor, since the launch of AstroSat (Rao et al. 2016; Chattopadhyay et al. 2019). CZTI is one of the two hard X-ray detectors sensitive in 20–150 keV. The instrument employs an array of CZT detectors, each 40 mm × 40 mm × 5 mm in size, totalling to a collecting of 924 cm². Each detector is further segmented spatially to 256 pixels with a pitch of ~2.5 mm. Use of collimator made of 0.07 mm tantalum and 1 mm aluminum sheets restricts the field of view of the instrument to ~4°. Details of the payload design and function are given in Bhalerao et al. (2017) and Rao et al. (2016). At energies beyond 100 keV, the increasing transparency of the collimators and the supporting structure enables CZTI to work as an all-
sky monitor. Because of this all-sky sensitivity, CZTI instrument since the launch of AstroSat has been working as an efficient GRB monitor with around \( \sim 83 \) GRB detections per year.\(^1\)

In the last one year, we have explored a number of new techniques in the spectral analysis for bright ON-axis sources like Crab and Cygnus X-1 (Chattopadhyay et al. 2021, under preparation). We also identified a number of possible improvements in the AstroSat mass model for better spectroscopic and polarimetry analysis for these sources. Implementation of these new techniques (listed below) will yield a significant improvement in the overall spectro-polarimetric sensitivity of GRBs detected by the CZTI.

- After the launch of AstroSat, \( \sim 20\% \) of the CZTI pixels were found to have electronic gains significantly lower than the ground calibrated gain values. Majority of these pixels now possess gain around 2–4 times lower than expected. However, the gain for these pixels is now stable since launch i.e. the gain change was a one-time phenomenon whose origin remains unknown. As a result of the lower gain, these pixels have a higher energy threshold of \( \sim 60 \) keV for X-ray photon detection but are also sensitive to photons of much higher energies up to \( \sim 800 \) keV. We refer to these pixels as low-gain pixels, which were originally excluded from any scientific analysis. However, after a careful and detailed analysis of the events from these pixels, here we attempt to include these pixels to increase the spectroscopic energy ranges for GRBs.

- From the Detector Plane Histogram (DPH) images of the valid Compton scattered events, we further identify the noisy pixels giving rise to 2-pixel events. Filtering out this ‘Compton noise’ is otherwise not removed from the standard noise rejection algorithm.

The new techniques allow us to explore the capability of CZTI as a sub-MeV GRB spectrometer. In the standard CZTI analysis pipeline, the prompt emission spectroscopy of the bursts are limited only in 100–200 keV whereas even with the 2-pixel Compton scattering events, the spectroscopy can only be extended up to \( \sim 350 \) keV. With the utilization of the low-gain pixels, the spectroscopy of the GRBs are now extended all the way up to \( \sim 1 \) MeV. There are three different ways the CZTI instrument provides spectroscopic information for the GRBs: (1) 1-pixel or single pixel events from CZT detectors in 100–900 keV, (2) 2-pixel or Compton scattering events from CZT detectors in 100–700 keV which are used to extract polarization information and (3) four CsI-Veto detectors below the CZTI sensitive in 100–500 keV. We use the AstroSat mass model to generate the effective area as a function of energy and response matrix for each of these spectroscopic techniques and perform broadband spectral analysis along with Fermi and Swift-BAT data. Proper spectral fits and constraining the spectral parameters critically depend on the correct estimation of response matrix elements which are different for different GRB direction with respect to the satellite orientation. Although the mass model has been validated and tested in detail using imaging method (Mate et al. 2021), spectroscopic analysis of the eleven GRBs which cover the full sky with respect to the AstroSat satellite indirectly tests the mass model further. This also helps in identifying the shortcomings in some parts of the mass model and quantifying those from the spectral fits. CZTI sub-MeV spectroscopy is particularly valuable for those GRBs which are detected by AstroSat and Niel Gehrels Swift BAT but not by Fermi, as it allows us to constrain the spectral parameters including the peak energy in the energy range (15–900 keV), which otherwise generally is not possible because of the narrow energy range of BAT. In this article, we explore CZTI as a sub-MeV spectroscopy and report the spectroscopic measurements for the eleven bright GRBs detected in the first year of CZTI operation with the implementation of these new developments for the entire burst time interval which is obtained using the Bayesian block technique on the GRB single event data. The new techniques and the burst selection methods are described in Section 2 In Section 3, we describe the spectroscopy methods followed by broadband spectral analysis in Section 4. While this article primarily outlines the methodologies of sub-MeV spectroscopy for GRBs, we plan to apply the new techniques to a sample of \( \sim 20 \) bright GRBs detected in last five years of operation of AstroSat.

2. New techniques in the spectrum analysis

In this section, we describe the new techniques implemented in the spectral analysis compared to that discussed in Chattopadhyay et al. (2019). In the previous polarimetry reports on AstroSat GRB by Chattopadhyay et al. (2019); Chand et al. (2018, 2019); Sharma et al. (2019), we utilized only 75–80% of the

\(^1\)http://astrosat.iucaa.in/czti/?q=grb.
CZTI collecting area consisting only the ‘spectroscopically good’ pixels. A fraction of CZTI pixels are found to have lower gains (gain value 3–4 times lower than that of the normal or good pixels) and therefore are sensitive at higher energies. We performed a detailed characterization of these pixels and utilize them in the spectrum analysis extending the overall spectroscopic energy range to \( \sim 1 \text{ MeV} \). We discuss these new developments below along with our new strategy of selecting the burst interval for spectroscopic analysis of the GRBs.

2.1 Characterization of low-gain pixels

From the detector plane histogram (DPH) of the onboard data, it was seen that the count rate in some spatially clustered pixels were significantly lower compared to the mean count rate (see Fig. 1). Even though most of the pixels are found in clusters, there are instances of isolated pixels as well. These pixels also did not show the alpha tagged line at 60 keV from the on board calibration source \(^{241}\text{Am} \), indicating that the gain has shifted at least by a factor of two or three (hereafter we refer to these pixels as low-gain pixels). The reason for the shift is unknown, however since no shift was seen in the laboratory measurements during calibration and appeared right after the launch, mechanical stress during the launch is thought to be one of the possibilities.

From the light curve analysis from the low-gain pixels with different time bins, we found that the count rates detected by these pixels are of Poissonian nature and therefore the detected events are not spurious pixel noise and could be real X-ray events.

Because these pixels consist almost 20% of the CZTI active area, we explored the possibility of characterizing the pixels in detail. In absence of any mono-energetic line at higher energies to calculate the correct gain for the low-gain pixels, we compare the overlapping region of the continuum spectrum of these pixels and the spectroscopically good pixels. For that purpose we first fitted the good pixel spectra for each of the 64 detector modules with an empirical model (red) consisting of three Gaussian: (1) Tantalum line at 54 keV, (2) a bump structure near the tantalum line and (3) an arbitrary line around 90 keV which is most likely a proton induced background feature (Odaka et al. 2018) and a broken power law (break energy around 140 keV which denotes the onset of falling detection efficiency for the 5 mm thick CZT detectors). This template has been used to compare the spectra of the low-gain pixels to estimate their gains (see text for more details).

![Figure 1](image1.png)

**Figure 1.** The detector plane histogram (DPH) of all the CZT detector quadrants for the obsID: 9000000618 (data from 2016 August). The lower count rates detected in a fraction of the pixels are seen as patches in the DPH which is because of the relatively higher gain values of the pixels. The color bars indicate the count rate.

![Figure 2](image2.png)

**Figure 2.** Continuum spectra from the spectroscopically good pixels (in blue) for one of the detector modules (data taken from July 2016). The spectrum is fitted with an empirical model (red) consisting of three Gaussian: (1) Tantalum line at 54 keV, (2) a bump structure near the tantalum line and (3) an arbitrary line around 90 keV which is most likely a proton induced background feature (Odaka et al. 2018) and a broken power law (break energy around 140 keV which denotes the onset of falling detection efficiency for the 5 mm thick CZT detectors). This template has been used to compare the spectra of the low-gain pixels to estimate their gains (see text for more details).

thick CZT detector and therefore can also be used to calibrate the low-gain pixels along with the continuum comparison. The strong line around 88 keV seen in the spectra is supposed to originate from high
energy particle induced tellurium activation \(^{127m}\text{Te}\) with half life of \(9.17 \times 10^6\) seconds (Odaka \textit{et al.} 2018). We also see a hint of a line feature around 145 keV which could also be from activated tellurium \(^{125m}\text{Te}\) with half life of \(4.96 \times 10^6\) seconds). Because of the large half life of the isotopes, we see the lines even far from the SAA region where the activation is supposed to take place (Odaka \textit{et al.} 2018). Since the number of good pixels vary in each module, the count rate was normalised by the total number of good pixels in that module.

In order to have sufficient statistics in the spectra of both good and low-gain pixels, we took a long one month data (\(\sim 1\) million seconds of exposure). The South

\begin{figure}[h]
\centering
\includegraphics[width=\textwidth]{figure3}
\caption{Spectra of three low-gain pixels of type I before and after applying gain correction given in left and right panels respectively. \textit{Top}: Pixel number 161 from module 4, \textit{middle}: pixel number 248 from module 5, and \textit{bottom}: pixel number 45 from module 13. The red lines are the empirical models used to compare the overlapping region of 45–180 keV of the low gain pixels. After comparison, the fitted gain shift factors (a multiplication factor to the ground calibrated gain) are found to be between 0.8 and 1.5 for the type I low gain pixels.}
\end{figure}
Atlantic Anamoly (SAA) regions are normally excluded in the raw data itself based on the count rates from an on board charge particle monitor. In addition to that, a time interval of 500 seconds was ignored before and after the already excluded SAA region in order to filter out the high particle background regions. The fitted module wise good pixel models were then used to compare the spectra of each of the low-gain pixels in 100–180 keV range and reduced $\chi^2$ values were calculated by varying a multiplication factor to the ground calibrated gain of the low-gain pixels in the range of 0.8–5.0 at an interval of 0.01. We call this multiplication factor to the gain as ‘gain shift factor’. Based on the fitting results, we classified the low-gain pixels into three subcategories:

1. **Low-gain pixels type I**: These pixels were found to have gain shift factor between 0.8 and 1.5 and are seen to have spectral features like the tantalum

![Figure 4](image_url)

*Figure 4.* Same as Fig. 3 but for three type II low-gain pixels (top: pixel number 223 from module 13, middle: pixel number 0 from module 5, and bottom: pixel number 1 from module 5). For type II low-gain pixels, we found the fitted gain shift factors between 1.5 and 4.
gains very close their ground calibration values, we plan to calibrate them with the on board calibration source for further validation, details of which will be presented elsewhere (Mithun et al., in prep.).

(2) Low-gain pixels type II: These pixels were found to have relatively higher gain shift values between 1.5 and 5.0. Comparison of the continuum spectra in 100–180 keV before and after gain correction is shown in Fig. 4.

(3) Low-gain pixels type III: For a fraction of pixels we could not get satisfactory fit in the common 100–180 keV range even for the maximum gain shift values. These pixels are ignored from any further analysis.

We carried out the analysis for each of the five years of CZTI data (normally June/July of each year depending on the data availability) to check for repeatability or any possible time evolution in the obtained gain values for the type I and type II low-gain pixels. We use the gain list from the year of detection of a given GRB (note for this paper we use gain list of the year 2016 as all the GRBs analyzed here are detected in 2016). In future, we plan to characterize the low-gain pixels (particularly the type II pixels) using various particle-induced radioactivation background lines (Odaka et al. 2018) for further verification. It might be possible to further verify the gain values by looking at the Crab pulse profile from these pixels and calculate the ratio of pulsed fractions in two pulses as they are known to be energy dependent. We also plan to validate the gain values of the type I pixels by investigating the alpha tagged spectra from these pixels.

In order to boost the confidence in the use of low-gain pixels, we attempted to reconstruct the Crab pulse profile using these pixels after gain correction. Figure 5 shows the pulse profile of Crab pulsar in low-gain pixels from all the CZTI quadrants during a /C24 78 ks observation on 14th January 2017. This further verifies that the events from these pixels are genuine X-ray events and not random noise.

We used the crab ephemeris at MJD 57769.0 from Lyne et al. (1999). The events are folded from AstroSat time 209507728 seconds (marked as zero). Each CZTI quadrant is shadowed by different degree for each GRB according to its location with respect to the spacecraft giving rise to unequal flux levels in different CZTI quadrants.

![Figure 5](image1.png)

**Figure 5.** The pulse profile of Crab pulsar in low-gain pixels (blue) of all the CZT quadrants after gain correction. For comparison, the pulse profile in the spectroscopically good pixels are plotted against it (red).

![Figure 6](image2.png)

**Figure 6.** Light curve of GRB 160821A in the low-gain pixels with corrected gains. Different colors represent the four different CZTI quadrants as indicated inside the plot. The time axis is plotted from AstroSat time 209507728 seconds (marked as zero). Each CZTI quadrant is shadowed by different degree for each GRB according to its location with respect to the spacecraft giving rise to unequal flux levels in different CZTI quadrants.

In order to boost the confidence in the use of low-gain pixels, we attempted to reconstruct the Crab pulse profile using these pixels after gain correction. The light curve of GRB 160821A in the low-gain pixels with corrected gains is shown in Fig. 6. The four different CZTI quadrants as indicated inside the plot. The time axis is plotted from AstroSat time 209507728 seconds (marked as zero). Each CZTI quadrant is shadowed by different degree for each GRB according to its location with respect to the spacecraft giving rise to unequal flux levels in different CZTI quadrants.

The pulse profile of Crab pulsar in low-gain pixels from all the four CZTI quadrants during a /C24 78 ks observation on 14th January 2017. This further verifies that the events from these pixels are genuine X-ray events and not random noise.

We used the crab ephemeris at MJD 57769.0 from Lyne et al. (1999). The events are folded from AstroSat time 209507728 seconds (marked as zero). Each CZTI quadrant is shadowed by different degree for each GRB according to its location with respect to the spacecraft giving rise to unequal flux levels in different CZTI quadrants.

The light curve of GRB 160821A in the low-gain pixels with corrected gains is shown in Fig. 6. The four different CZTI quadrants as indicated inside the plot. The time axis is plotted from AstroSat time 209507728 seconds (marked as zero). Each CZTI quadrant is shadowed by different degree for each GRB according to its location with respect to the spacecraft giving rise to unequal flux levels in different CZTI quadrants.
count rate is normalized by the total number of low-gain pixels in a quadrant. Detection of astrophysical sources in low-gain pixels therefore presents a strong case in using them for future spectral analysis.

2.2 Compton noise

CZTI has already been demonstrated as a sensitive ON-axis and GRB polarimeter in 100–350 keV in Vadawale et al. (2018) and Chattopadhyay et al. (2019) respectively, where the Compton scattered events are used to generate the azimuthal angle histogram. The same Compton events can be used in spectroscopy of the GRBs. These events are selected through strict Compton kinematics criteria:

- identify the adjacent 2-pixel events from 20 μs coincidence window both from the spectroscopically good pixels and low-gain pixels,
- impose criteria of ratio of the energies deposited in two pixels between 1 and 6 in order to filter out the noisy chance events. This is motivated by the fact that in a true Compton scattering event, the electron recoil energy deposited in one of the pixels, is much lower than the scattered photon energy deposited in the other pixel.

In spite of the strict selection criteria, there is still a significant amount of overlapping noise events. Neighbouring pixels can flicker at time scales lower than the coincidence time window of 20 μs causing some of these events to permeate into the Compton event selection and thus causing instrumental artifacts in the modulation curve. A DPH showing outliers in 2-pixel events is shown in Fig. 7. These events can be identified as outliers from the DPH of neighbouring 2-pixel events and can be removed from further analysis. Threshold for an outlier is kept at four sigma and three sigma from the mean for normal and low-gain pixels respectively. Due to the difference in count rate between the side and corner pixel double events, we identify the noisy pixels in the side and corner pixels separately. When a pixel is identified as noisy, no events from that pixel is considered for further analysis. Further details on the Compton noise analysis can be found in Ratheesh et al., 2020, this issue.

2.3 Selection of burst interval

In this work, the spectrum analyses are conducted on the time integrated emission of the bursts. The time interval corresponding to the integrated emission is chosen by employing the Bayesian block algorithm (Scargle 1998; Scargle et al. 2013; Burgess 2014) of time binning on the single pixel event data of the bursts. The block with the minimum probability density value corresponding to the background region is taken as the guide to decide the start and stop times of the integrated emission. The onset time of the first block with the probability density greater than that of the background which is closer to the onset time of the burst and the end time of the last block after which the background continues are considered as the start and stop times of the time interval of integrated emission respectively (Fig. A1 in Appendix).

In the next section, we describe the methodology of spectroscopy using 1-pixel and 2-pixel CZTI events and CsI-veto detected events followed by broadband spectroscopy results for the eleven bright GRBs detected in 2015–2016. For CZTI events, we utilize both the standard good pixels and the newly calibrated low-gain pixels to extend the energy spectra to sub-MeV region.

Figure 7. Detector plane histogram of the neighbouring 2-pixel Compton events for the 3rd CZTI quadrant. The plotted data belongs to obsID: 9000000618 (data from 2016 August). The color bar indicates count rate. The brighter spots in the image correspond to the Compton noisy events arising from noisy neighboring pixels. These events are removed from further analysis.
Figure 8. GRB light curves from CZTI 1-pixel (red) and 2-pixel events (black points) for the 11 GRBs. The time intervals of the bursts are obtained from the Bayesian block analysis on the 1-pixel CZTI light curves as shown by the vertical dashed lines. The ‘zero’ denoted in the time-axis stands for the trigger time reported by the Fermi-GBM.
3. Methodology for spectroscopy

3.1 Spectroscopic response

The 2D spectral responses for CZTI 1-pixel, 2-pixel and CsI/veto spectroscopy are generated using GEANT4 simulation. Here we outline the basic steps of response generation. Response is computed using GEANT4 mono-energy simulations of the full AstroSat mass model at specific $\theta$ and $\phi$ viewing angles for each GRB ($\theta$ and $\phi$ for a given GRB are provided by either Swift or Fermi). The mono-energetic lines for simulations were selected between 100 keV and 2 MeV at every 20 keV till 1 MeV and at every 100 keV in 1–2 MeV, totalling around 56 mono-energies. Simulation is done for a large number of photons ($10^9$ photons for each energy) in order to have a statistically significant energy distribution in CZTI for each mono-energetic line. The simulation file contains information of total seven interactions or steps for each incident photon ($x$, $y$, $z$-position of interactions in CZTI and deposited energy in each interaction, see Chattopadhyay et al. (2014)) in CZTI modules. We add up the energies from all the interactions happening within a pixel of 2.5 mm $\times$ 2.5 mm in Interactive Data Language (IDL\textsuperscript{2}) based routine outside the GEANT4. We apply the same CZTI pixel-level LLD (Lower Level Discriminator) values in the simulation data whereas the ULDs (Upper Level Discriminator) were computed from actual observational data for each module and is applied to simulation data accordingly. From this event list, the 1-pixel and 2-pixel events are separated and processed differently for final response generation. For 1-pixel events, the distribution of deposited energies is calculated at a bin size of 1 keV from 0 keV to 1000 keV (total 1000 bins) for each of the 56 mono-energies.

It is to be noted that Geant4 simulation takes care of all types of interactions with appropriate probabilities including photoelectric, Compton, Rayleigh inside CZTI and photons scattered from the spacecraft or other surrounding payloads to CZTI. Because of these multiple interactions and scattered events from surrounding materials, the distribution of deposited energy in CZTI is broad and non-gaussian. However, the large number of photon simulation gives sufficient statistics to obtain the correct energy distribution in the full range of 100 bins for all 56 mono-energies. The 2D matrix ($56 \times 1000$) of deposited energy distributions for the mono-energetic lines is then convolved with a Gaussian function of appropriate width to generate the 1-pixel spectral response or the Redistribution Matrix File (RMF). On the other hand, we apply the Compton kinematics criteria on the 2-pixel events to select the valid Compton events. The energies of the two pixels are then added up to calculate the total deposited energy. The deposited energy distributions for the 56 mono-energies are then convolved with a Gaussian to obtain the 2-pixel response. The CsI (or veto) spectral responses are generated for each quadrant in the same fashion using the same AstroSat mass model simulation data where we only consider events and associated energies deposited in the CsI detectors to estimate the deposited energy distribution. It is to be noted that we use a $\mu\tau$ and charge diffusion based line profile model (Chattopadhyay et al. 2016) for mask weighted response below 150 keV, whereas for this work, we use a simple Gaussian model for simplicity.

3.2 Single pixel (1-pixel) spectroscopy

Because the CZTI surrounding structures and the collimators become increasingly transparent above 100 keV, the spectral analysis of the GRBs starts from 100 keV and extends to 900 keV after incorporating the low-gain pixels. Detection efficiency of a 5 mm CZT drops below 10% above 1 MeV resulting in a low signal-to-noise ratio at those energies. The single pixel events are selected such that there are no other events reported in 100 $\mu$s time window on either side of the event. Energies deposited in all such events in the full burst region (interval obtained from Bayesian block analysis) are used to generate the spectrum with a 10 keV binning.

The 1-pixel light curves and the selected time intervals are shown in Fig. 8 (red solid lines). The background spectrum is constituted by selecting at least 300 seconds of time window from the pre and post-burst regions.

We quantify the systematics in the 1-pixel spectral data arising due to the uncertainties and inaccuracies in the AstroSat mass model and the CZTI detector via the analysis of the spectral data of GRBs detected at different incoming orientations. We use Band model (Band et al. 1993) to fit the spectra while keeping the power law indices ($\alpha$ and $\beta$) and peak energy ($E_{\text{peak}}$) frozen at the values reported by either the Konus Wind or Fermi spectral analysis, and the normalisation of the Band model is left free.

\textsuperscript{2}Research Systems Inc. (1995). IDL user’s guide: interactive data language version 4. Boulder, CO: Research Systems.

For the different GRBs, listed in Table 1, detected at different orientations including most of the incoming angles around the spacecraft, once obtaining a best fit, we find unresolvable discrepancies between calculations and the data, i.e., systematic errors. Without knowing or assuming the origin of these features, we characterize the effect by adding systematic errors in an incremental fashion until we achieve a uniform residual with a reduced $\chi^2$. We, therefore, add 10–15% systematic to the 1-pixel spectroscopic data for all the GRBs to take care of the inaccuracies in the AstroSat mass model.

For example, the spectral fits with the respective residuals obtained for the GRB 160623A (left) and GRB 160802A (right) that are detected on either side of the spacecraft are shown in the Fig. 9 where 1-pixel spectra in 100–900 keV obtained from the full burst region are shown in red crosses.

3.3 Compton (2-pixel) spectroscopy

The Compton spectroscopy is carried out in the energy range of 100–700 keV since above 700 keV there is no sufficient Compton scattering efficiency of CZTI detectors. The 2-pixel Compton events are identified from adjacent pixel events within 20 $\mu$s coincidence window with an additional Compton kinematics criteria of ratio of two deposited energies between 1 and 6 (also discussed in Chattopadhyay et al. (2014)). The energies from the two events recorded are added up to get the total energy and therewith the spectrum with a bin size of 10 keV.

The systematics involved in the Compton spectral data are assessed using the same methodology adopted for 1-pixel spectral data (Section 3.2). The spectral fits and the residuals obtained for the Compton spectra of GRB 160623A and GRB 160802A in 100–700 keV are shown in red data points in Fig. 9. Similar to the 1-pixel spectra, we find reasonable fit to the data and agreement with Fermi and Konus-Wind.

3.4 CsI (or Veto) spectroscopy

There are four CsI(Tl) scintillator detectors (each 167 mm $\times$ 167 mm in size and 2 cm in thickness) below CZTI quadrants to veto the high energy particle induced background events reported in both CZTI and CsI detectors (Bhalerao et al. 2017; Rao et al. 2016). The veto detectors were initially not meant for spectroscopy. However since the detectors possess sufficient detection efficiency in the sub-MeV region, we explored the possibility of using them for spectroscopy to enhance the overall spectroscopic sensitivity. The existing CZTI pipeline provides the veto spectrum at every second. We employ the available data to generate spectrum for each
Veto detector in a similar way that is used for CZTI single pixel events. However, we do not use the poorly calibrated 4-th Veto quadrant for spectroscopy. It is to be noted that the Veto spectrum consists of all interactions in the CsI detectors and different from the Veto tagged events where the both CZTI and Veto are triggered due to simultaneous events recorded in those detectors.

For all the GRBs detected from the rear side of the spacecraft, we find the observed spectra to be flatter than the response folded model. An example is shown in the top-left spectral plot of Fig. 10 for GRB 160623A which is detected at $\theta$ of $\sim 140^\circ$. We find an identical systematic trend in all the back side GRBs. However, we do not attribute the systematic to the mass model as CZTI 1-pixel and 2-pixel spectral fits for back side GRBs do not show such systematic trend in the residuals. On the other hand, the trend is significantly lower in Veto detectors for the front side GRBs. Therefore we believe that this systematic is originated in the CsI detectors but primarily for detections from back side. CsI detectors are scintillator detectors where the scintillation light is collected by the PMTs (2 PMTs for each of the 4 CsI detectors). At lower energies ($\sim 100$ keV), the number of scintillation photons generated is lower than that at higher energies. Given the fact that there are only two PMTs to collect the scintillation photons, the detection probability of the GRB photons at lower energies is expected to be relatively low. We also note that the detectors were initially not meant for spectroscopy.

Figure 10. Top left: The count spectra (upper panel) and their respective residuals (lower panel) obtained for the three quadrants of the Veto detectors (black: quadrant A, red: quadrant B and green: quadrant C) for GRB 160623A (detected from the back side of CZTI). We see a systematic trend in the residuals possibly due to lower detection probability by the scintillators around 100 keV which improves at higher energies. Top right: Same as the left figure but after implementing an energy-dependent correction ($1 - e^{-\text{Energy}/E_0}$), where $E_0^{-1} = 0.0045$ keV$^{-1}$ (see text for more details). Bottom: same as the top figure but for GRB 160802A (detected from the front side) after implementing the energy-dependent correction with a higher value of $E_0^{-1} = 0.01$ keV$^{-1}$.
Figure 11. The count spectra (upper panel) and the respective residuals (lower panel) obtained for the broad band joint spectral analysis consisting of Fermi + CZTI data (+ BAT data in cases where it is available) for GRB 151006A, GRB 160106A, GRB 160509A, GRB 160325A, GRB 160802A, GRB 160821A and GRB 160910A are shown.
and therefore the number of readout photo-multiplier tubes and optical coupling between the crystal and the photo-multiplier tubes (PMTs) were not optimized to enhance the detection probability. The light collection efficiency might be significantly compromised for events happening in the back side of CsI because of the absence of optical reflecting coating on the back surface and a relatively higher level of cover shielding on the back side near the PMTs (light collecting area is relatively lower on the back side).

To take care of this, we multiply the photon detection probability (represented by an empirical term, $1 - e^{-\text{Energy}/E_0}$) to the model (same as multiplying to the CsI detector response) to mimic for an energy dependent systematic where the value of $E_0^{-1}$ depends on the location of transient observed with respect to CZTI. For the front side GRBs (example shown in the bottom panel of Fig. 10 for GRB 160802A) i.e., $\theta < 60^\circ$ the value of $E_0^{-1}$ is found to be around 0.01 keV$^{-1}$ which gives 90% detection probability at around 200 keV, whereas for the orthogonal GRBs, i.e., $90^\circ < \theta < 110^\circ$, the value of $E_0^{-1}$ comes out to be around 0.008 keV$^{-1}$. For the back side GRBs, value of $E_0^{-1}$ is found to be around 0.0045 keV$^{-1}$ signifying poor detection probability (90% detection probability at around 600 keV).

Since we get similar values of $E_0^{-1}$ for front, back and orthogonal GRBs, we plan to incorporate the exponential feature observed in the Veto detectors in the response itself. We also include an additional 5% systematic in the data in case of back side GRBs.

![Figure 12. The count spectra (upper panel) and the respective residuals (lower panel) obtained for the joint spectral analysis consisting of Niel Gehrels Swift BAT + CZTI data using the spectral model band function for the bursts GRB 160131A (top left), GRB 160607A (top right) and GRB 160703A (bottom) are shown. Here we demonstrate that for bursts without Fermi detections, the usage of CZTI data extending until 900 keV along with BAT, enables us to constrain the $E_{\text{peak}}$ of the GRB spectrum.](image-url)
4. Results I: Broadband joint spectroscopy of GRBs

With a fair assessment of the systematics present in the CZTI and Veto spectral data, we now conduct the broadband joint spectral analyses involving the spectral data from Fermi, Neil Gehrels Swift BAT, along with CZTI data including the single, Compton and Veto for the time integrated emission of different GRBs. We analyse the time integrated spectrum of 10 GRBs that were detected by CZTI in the first year of its operation (2015–2016). The time interval of the integrated emission is selected using Bayesian block binning technique and described in Section 2.3.

The Fermi spectral data includes two bright sodium iodide (NaI) detectors with source angle less than (<60°) and the brightest bismuth germanate (BGO) detector (Gruber et al. 2014). In case of GRB151006A, GRB160509A and GRB160821A, the low energy Large Area Telescope (LLE) data are also used. The Fermi spectral files are extracted using Fermi Burst Analysis GUI v. 02-03-00p33 (gtburst4).

The Swift BAT spectral files are prepared by the standard methodology.5

The spectral analyses are performed using the X-Ray Spectral Fitting Package (XSPEC, Arnaud 1996) version: 12.11.0 and have followed chi-square statistics. Both BAT and CZTI spectral files are compatible with Gaussian statistics, however, the GBM and LLE files are consistent with Pgstat wherein the background and signal are assumed to be Gaussian and Poissonian respectively. Therefore, using Heasoft Ftool GRPPHA,6 we rebinned both GBM and LLE spectral files such that each energy channel contains a minimum of 20 photons.

The spectral fit results and the respective residuals obtained for the best fit empirical functions like Band function (Band) and cutoff power law (CPL) are reported in Table 1 and shown in Figures 11, 12 and 13 respectively. We find that residual obtained for CZTI spectral data are consistent with those obtained for Fermi. The residuals are found within 3σ for CZTI data.

The small energy window of Swift BAT (15–150 keV) generally does not allow us to constrain the $E_{\text{peak}}$ of the spectrum in cases where there is only BAT detection. In

conducted the spectral analysis using Swift 160131A, where case of GRB 160131A, GRB 160607A and GRB 160703A, the effective area correction factors obtained for the different CZTI datasets: single (black square), Compton (blue diamond), Veto Q1 (yellow circle), Veto Q2 (purple triangle) and Veto Q2 (red star) with respect to the Fermi bright NaI detector of (purple triangle) and Veto Q2 (red star) with respect to the Compton (blue diamond), Veto Q1 (yellow circle), Veto Q2 (purple triangle) and Veto Q2 (red star) with respect to the Fermi bright NaI detector of. The effective area correction factors obtained between BAT and CZTI are shown in Fig. 14, where constant for BAT is frozen to unity. The energy flux estimated in the range of 10–1000 keV for the bursts are reported in the Table 1.

During the joint spectral analysis using different detectors, we have tied the spectral parameters of all the detectors including the normalisation of the spectral model. The difference in count rates in different detectors are taken care of by including the effective area correction factor along with the spectral model that is used to analyse the data. To estimate the effective area correction factor between the different detectors, we multiply an energy independent constant factor to the spectral model during the fitting process. The effective area correction factor obtained between Fermi and the different datasets of CZTI except in GRB 160131A, GRB 160607A and GRB 160703A where the values are obtained with respect to Swift BAT are shown.

For GRB 151006A and GRB 160325A, both Fermi and BAT observations are available. So, in these cases of GRB 160607A, GRB 160703A and GRB 160131A, where Fermi detections were not available, we conducted the spectral analysis using Swift BAT along with CZTI data. We demonstrate that the usage of CZTI data extending until 900 keV allows us to well constrain the $E_{\text{peak}}$ of the spectrum. The effective area correction factor obtained between BAT and CZTI are shown in Fig. 14, where constant for BAT is frozen to unity. The energy flux estimated in the range of 10–1000 keV for the bursts are reported in the Table 1.

During the joint spectral analysis using different detectors, we have tied the spectral parameters of all the detectors including the normalisation of the spectral model. The difference in count rates in different detectors are taken care of by including the effective area correction factor along with the spectral model that is used to analyse the data. To estimate the effective area correction factor between the different detectors, we multiply an energy independent constant factor to the spectral model during the fitting process. The effective area correction factor obtained between Fermi and the different datasets of CZTI except in GRB 160131A, GRB 160607A and GRB 160703A where the values are obtained with respect to the Swift BAT are shown in Fig. 14. On average, the normalisation estimates of the empirical function fits done to the single, Compton, Veto 1, 2, and 3 data are found to vary around 20%, 55%, 55%, 40% and 40% of the normalisation estimate of the brightest Fermi NaI detector respectively. While with respect to the BAT detector, the normalisation estimates for the single, Compton, Veto 1, 2, and 3 events, vary around 40%, 140%, 85%, 20% and 70% respectively. In certain GRBs, we observe low normalizations for Compton and Veto data which results in an effective area correction factor >2. The cause of such cases are being studied.

For GRB 151006A and GRB 160325A, both Fermi and BAT observations are available. So, in these

![Figure 14. The effective area correction factors obtained for the different CZTI datasets: single (black square), Compton (blue diamond), Veto Q1 (yellow circle), Veto Q2 (purple triangle) and Veto Q2 (red star) with respect to the Fermi bright NaI detector of](image)

Table 2. The band model fit comparison between BAT + CZTI and Fermi alone analysis of the bursts GRB 151006A and GRB 160325A.
GRBs, we conduct a joint spectral analysis of BAT and CZTI data and then compare the spectral fit results with that obtained using Fermi GBM data alone. We are able to ascertain the $a$, $E_{\text{peak}}$ and normalization values which are reasonably consistent with Fermi GBM results, within 90% error limits (Table 2 and Fig. 13). This further endorse the capability of CZTI as a sub-MeV spectrometer along with BAT to determine the GRB spectrum.

We note here that being opaque below 100 keV, CZTI spectrum alone cannot measure the GRB spectral parameters fully. On the other hand, if we assume canonical values for the power law indices ($\alpha = -1$ and $\beta = -2.5$) of the Band function, we can constrain the $E_{\text{peak}}$ and normalisation of the spectrum. In certain cases, the $E_{\text{peak}}$ estimates are found to lie close to the edge or outside the energy window of CZTI (e.g. GRB160509A and GRB160821A). In Fig. 15, the energy fluxes estimated in the energy range 100 keV–1000 keV for spectral fits of CZTI data alone (where the power law indices are frozen to the canonical values), are plotted against the respective energy flux estimated from the Fermi data only spectral fits (where all the fit parameters are left free) of the different bursts. We find the CZTI flux estimates are consistent within 2σ scatter around the line denoting CZTI energy flux is equivalent to Fermi flux.

5. Summary and future plan

CZT-Imager on board AstroSat has been a prolific GRB monitor with around detection of nearly 83 GRBs per year. In this article, we explored the spectroscopic sensitivity of CZTI in the sub-MeV region by attempting spectroscopic analysis for some of the bright GRBs detected in the first year (October 2015–September 2016) of AstroSat operation. The improvement in the spectroscopic sensitivity has been possible because of (1) inclusion of the low-gain CZTI pixels after a thorough calibration which consists of around 20% of the CZTI detection area, and (2) identification and removal of 2-pixel noisy events. Both the methods improve the S/N of the bursts significantly and in particular the low-gain pixels enable the spectroscopy all the way up to 900 keV (1-pixel Compton spectroscopy: 100–700 keV, 1-pixel spectroscopy: 100–900 keV). We also utilize the CsI (or Veto) detectors for spectroscopy in 100–500 keV to enhance the overall sensitivity.

In Section 4, we performed joint Fermi and AstroSat (and BAT wherever available) spectral analysis for 10 out of the eleven first year GRBs (except GRB 160623A where a concurrent observation with Fermi was not available) in the full burst region. We are able to obtain spectral fit parameter values that are in close agreement with those obtained in solo Fermi analysis. This provides

---

7The scatter is the standard deviation of the Gaussian fit to the distribution of the displacement of the CZTI measured flux from the Fermi flux and is found to be $\sigma = 0.21$. 

---

Figure 15. Above the CZTI flux estimates ($Y$) done for the spectral fits done to CZTI data alone versus the energy flux estimates done for Fermi ($X$) alone spectral fits are shown. The red (blue) shaded region marks the $1\sigma$ ($2\sigma$) scatter of the distribution of points around the $Y = X$ line shown in dotted red line.

Figure 16. Detection of GRB 160821A in the veto-tagged events. Different colours stand for different CZTI quadrants. The time-axis is plotted from AstroSat time 209507728 seconds (marked as zero) onward.
an independent validation of the AstroSat mass model, thereby boosting the confidence in the spectral analysis of the CZTI GRBs. Spectral validation of the mass model and availability of CZTI spectra up to 900 keV also allows to explore spectral study of the GRBs detected only by Swift-BAT and CZTI but not by Fermi. This aspect has been particularly demonstrated in the case of GRB151006A and GRB160325A where we find reasonably consistent spectral fit values for BAT + CZTI in comparison to solo Fermi data analysis of these bursts. Thus, the satisfactory spectral fits obtained in 15–900 keV (15–150 keV from BAT, 100–900 keV from CZTI) for GRB 160607A, GRB 160131A and GRB 160703A demonstrates the importance of CZTI sub-MeV spectroscopic capability particularly to characterize the GRBs that are not detected by Fermi. We also identify possible systematics involved in the mass model and attempt to quantify them (<15%) in the front and rear sides of the spacecraft.

This paper primarily describes the new methods of sub-MeV spectroscopy with CZTI. We are continuing to refine these methods further, and will extensively test them against a much larger sample of bright GRBs detected by CZTI in the last five years. We also plan to explore the feasibility of using the CZT detectors and the CsI detectors in Compton camera configuration to enhance the spectroscopic sensitivity of the instrument. From a preliminary analysis, we could successfully detect the GRBs in the veto-tagged events (Compton scattered photons from CZT detectors which are absorbed by the CsI detectors) after applying Compton scattering kinematic conditions (see Fig. 16). We plan to use the AstroSat mass model to generate response matrix for the veto-tagged events.
