The $K^0_SK^0_S$ final state in two-photon collisions is studied with the L3 detector at LEP using data at centre of mass energies from 91 GeV to 183 GeV. The $K^0_SK^0_S$ mass spectrum is dominated by the formation of the $f_2(1525)$ tensor meson whose two-photon partial width is measured. Clear evidence for destructive $f_2-a_2$ interference is observed. No signal is present in the region around 2.2 GeV. An upper limit for the two-photon partial width times the $K^0_SK^0_S$ branching ratio of the $f_{2}(2230)$ glueball candidate is then derived. An enhancement is observed around 1750 MeV. It may be due to the formation of a radial recurrence of the $f_{2}(1525)$ or to the $s\bar{s}$ member of the $0^{++}$ meson nonet.

1. Introduction

Electron-positron storage rings are widely used to investigate the behaviour of two-photon interactions via the process $e^+e^- \rightarrow e^+e^-\gamma^*\gamma^* \rightarrow e^+e^-X$, where $\gamma^*$ is a virtual photon. The outgoing electron and positron carry nearly the full beam energy and their transverse momenta are usually so small that they are not detected. This kind of event is characterised by an initial state $e^+e^-\gamma^*\gamma^*$, calculable by QED, and a low multiplicity final state. This process is particularly useful in the study of the properties of hadron resonances.

The total cross section $\sigma_T$ for the formation of a resonance $R$ is given by:

$$\sigma_T(e^+e^- \rightarrow e^+e^-R) = \int d^5L_{\gamma\gamma}\sigma(\gamma^*\gamma^* \rightarrow R)$$

where $d^5L_{\gamma\gamma}$ is the differential luminosity function giving the flux of virtual photons. For quasi-real photons $\sigma(\gamma^*\gamma^* \rightarrow R)$ is given by the Breit-Wigner formula:

$$\sigma = 8\pi(2J_R+1)\frac{\Gamma^2(R)\Gamma(\Gamma)}{(W_{\gamma\gamma}^2 - m_R^2)^2 + m_R^4\Gamma^2(R)}$$

where $W_{\gamma\gamma}$ is the invariant mass of the two-photon system, $m_R$, $J_R$, $\Gamma(\Gamma)$ and $\Gamma(R)$ are the mass, spin, two-photon partial width and total width of the resonance, respectively. Combining equations (1) and (2) leads to the proportionality relation

$$\sigma_T(e^+e^- \rightarrow e^+e^-R) = \mathcal{K} \cdot \Gamma(\Gamma)$$ (3)

where the proportionality factor $\mathcal{K}$ can be evaluated by a Monte Carlo integration. Equation (3) is used to determine the two-photon partial width of the resonance.

The quantum numbers of the resonance must be compatible with the initial state of the two quasi-real photons. A neutral, unflavoured meson with even charge conjugation and helicity-zero or two can be formed. In order to decay into $K^0_SK^0_S$, the resonance must have $J^{PC} = (\text{even})^{++}$.

For the $2^{++}$, $1^{3}P_2$ tensor meson nonet, the $f_2(1270)$, the $a_2^0(1320)$ and the $f_2'(1525)$ can be formed. However, since these three states are close in mass, interferences must be taken into account. According to SU(3), the $f_2(1270)$ interferes constructively with the $a_2^0(1320)$ in the $K^+K^-$ final state but destructively in the $K^0\bar{K}^0$ final state. Therefore, among the states of the tensor meson nonet, only the $f_2'(1525)$ was observed by previous experiments in the $K^0\bar{K}^0_S$...
Since gluons do not couple to photons, a pure glueball couples to two photons only via a box diagram and its two photon width is therefore expected to be very small. A state that can be formed in a gluon rich environment but not in two photon fusion has the typical signature of a glueball.

An analysis of the reaction $e^+ e^- \rightarrow e^+ e^- K^0_S K^0_S$ is presented here, where only the $K^0_S \rightarrow \pi^+ \pi^- \pi^\pm \pi^- \pi^\pm$ decay is considered. The data correspond to an integrated luminosity of 143 pb$^{-1}$ collected by the L3 detector at $\sqrt{s} = 91$ GeV and 52 pb$^{-1}$ at $\sqrt{s} = 183$ GeV.

A study of the $K^0_S K^0_S$ final state in two-photon collisions was already published by the L3 Collaboration [3] with a luminosity of 114 pb$^{-1}$ at $\sqrt{s} = 91$ GeV.

The L3 experiment is described in detail elsewhere [4]. In this analysis, the charged particle tracker is mainly used. It is composed by a silicon microstrip vertex detector and a multiwire drift chamber. The events are triggered by a low $p_t$ threshold charged-track trigger [5].

2. Event Analysis

In order to select $e^+ e^- \rightarrow e^+ e^- \pi^+ \pi^- \pi^+ \pi^- \pi^+ \pi^-$ events, we require:

- The total energy seen in the calorimeters must be smaller than 30 GeV to exclude annihilation events.
- There must be exactly four good charged tracks in the tracking chamber with a net charge of zero. A good track requires more than 20 hits out of a maximum of 62.
- The total momentum imbalance in the transverse plane must satisfy: $|\sum \delta \hat{p}_T|^2 < 0.1$ GeV$^2$.
- Events with photons are rejected. A photon is defined as an isolated shower in the electromagnetic calorimeter with an energy larger than 100 MeV.

The $K^0_S$’s are identified by requiring a secondary vertex distinct from the primary interaction point with a distance greater than 1 mm in the transverse plane. In order to select $K^0_S K^0_S$ exclusive events, we require:

- At least one of the two secondary vertices must be at a distance greater than 3 mm from the interaction point in the transverse plane.
- The angle between the flight direction of each $K^0_S$ candidate (taken as the line between the interaction point and the secondary vertex in the transverse plane) and the total transverse momentum vector of the two outgoing tracks must be less than 0.3 rad.
- Since the two $K^0_S$’s are produced back-to-back in the transverse plane, the angle between the flight directions of the two $K^0_S$ candidates in this plane is required to be $\pi \pm 0.3$ rad.
Events/10x10 MeV

Figure 2. $m(\pi^+\pi^-)$ at one secondary vertex versus $m(\pi^+\pi^-)$ at the other secondary vertex. There is a strong enhancement near the $K_S^0K_S^0$ point over a very small background.

Fig. 1 shows the $\pi^+\pi^-$ mass distribution with a 3 mm vertex cut for the $K_S^0$. Fitting this distribution, a mass resolution of $\sigma = 9.6 \pm 0.8$ MeV is found, consistent with the Monte Carlo simulation. The invariant masses of the two $K_S^0$ candidates must be inside a circle of 40 MeV radius around the $K_S^0K_S^0$ point (Fig. 2).

With these selection criteria, 253 events are found in the data sample. The background due to misidentified $K_S^0$ pairs is estimated to be negligible by a study of the $K_S^0$ sidebands. The background due to the $K_S^0K^\pm\pi^\mp$ final state is determined to be negligible by a Monte Carlo simulation. The beam-gas and beam-wall contributions are found negligible.

The resulting $K_S^0K_S^0$ invariant mass spectrum is shown in Fig. 3. The spectrum is dominated by the $f_2'(1525)$ resonance. The $f_2(1270) - a_0^0(1320)$ region shows the destructive $f_2 - a_0^0$ interference in the $K_S^0K_S^0$ final state [1]. A clear enhancement is visible in the 1750 MeV region. No excess is present around 2230 MeV.

A maximum likelihood fit using three Gaussians plus a constant is then performed on the $K_S^0K_S^0$ mass spectrum. The masses and widths of the Gaussians are left free in the fit. The fit is shown in Fig. 3 and the results are summarised in Table 1.

The $f_2'(1525)$ statistical significance is about 8 standard deviations, the statistical significance of the enhancement around 1750 MeV is about 6 standard deviations. From the fit $38 \pm 7$ events are found in the $f_2-a_2$ region.

In order to correct the data for the detector acceptance and efficiency, a Monte Carlo procedure
is used \[\[.\]\] The nominal \(f_2'(1525)\) parameters \[\[\]\] are used for the generation. The angular distribution of the two \(K_S^0\)'s in the two-photon center-of-mass system is generated according to phase space i.e. uniform in \(\cos \theta^*\) and in \(\phi^*\), where \(\theta^*\) and \(\phi^*\) are the polar and azimuthal angles taking the \(z\) direction parallel to the electron beam. In order to take into account the helicity of a spin-two resonance, a weight is assigned to each generated event according to the weight functions: \(w = (\cos^2 \theta^* - \frac{1}{3})^2\) for the helicity-zero contribution and \(w = \sin^4 \theta^*\) for the helicity-two contribution.

All the events are passed through the full detector simulation program and are reconstructed following the same procedure used for the data. Although the detector acceptance is rather high (15% for helicity-zero and 30% for helicity-two), the trigger efficiency (83%) and the analysis cuts (\(\sim 30\%\)) give a total efficiency of 3.9% for helicity-zero and 7.6% for helicity-two for the \(f_2'(1525)\) at \(\sqrt{s} = 91\) GeV. At \(\sqrt{s} = 183\) GeV the total efficiencies are 3.1% and 7.2% respectively.

3. Results

3.1. The \(f_2'(1525)\) tensor meson

In order to determine the helicity state, a study of the angular distribution of the two \(K_S^0\)'s from \(f_2'\) decay in the two-photon center of mass is performed. The experimental polar angle distribution is compared with the Monte Carlo in Fig. 4 for both the helicity-zero and helicity-two cases. The Monte Carlo distributions are normalised to the same number of events as the data.

The total cross section \(\sigma_T\) times the branching ratio \(Br\) into \(KK\) for the \(f_2'(1525)\) is measured using the formula
\[
\sigma_T \times Br = \frac{N_{\text{obs}} - N_{\text{back}}}{\mathcal{L} \varepsilon} \tag{4}
\]
where \(\mathcal{L}\) is the integrated luminosity and \(\varepsilon\) is the total efficiency. The number of signal events \(N_{\text{obs}} - N_{\text{back}}\) is determined from the maximum likelihood fit. From our data only \(\sigma_T \times Br(f_2' \rightarrow K_S^0K_S^0 \rightarrow \pi^+\pi^-\pi^+\pi^-)\) can be measured. Using the PDG value for \(Br(K_S^0 \rightarrow \pi^+\pi^-)\) and \(Br(f_2' \rightarrow KK) = 4 \times Br(f_2' \rightarrow K_S^0K_S^0)\) from isospin symmetry, \(\sigma_T \times Br(f_2' \rightarrow KK)\) can be determined.

The product \(\Gamma_{\gamma\gamma}(f_2') \times Br(f_2' \rightarrow KK)\) is measured from the cross section using the formula
\[
\Gamma_{\gamma\gamma}(f_2') \times Br(f_2' \rightarrow KK) = \frac{\sigma_T \times Br(f_2' \rightarrow KK)}{K} \tag{5}
\]
where the proportionality factor \(K\) is evaluated by Monte Carlo integration. Two separate measurements are performed for data collected at \(\sqrt{s} = 91\) GeV and \(\sqrt{s} = 183\) GeV. The results are in very good agreement with the published value \(\Gamma_{\gamma\gamma}(f_2') \times Br(f_2' \rightarrow KK) = (0.093 \pm 0.018 \pm 0.022)\) keV under the hypothesis of a pure helicity-two state.
3.2. The 1750 MeV region

The enhancement around 1750 MeV may be due to the formation of a radially excited \( f_2' \) state, according to theoretical predictions \([9]\). However, the 1750 MeV region is very interesting especially looking at the recent results by the Crystal Barrel Collaboration \([10]\). They report the observation of three \( J^{PC}=0^{++} \) states the \( a_0(1450) \), the \( f_0(1370) \) and the \( f_0(1500) \). In the scenario presented in \([11]\) the \( a_0(1450) \) is the isovector member of the \( 0^{++} \) meson nonet while the \( f_0(1370) \) and the \( f_0(1500) \) cannot both be isoscalar members of the nonet. The \( f_0(1370) \) is very likely mainly composed by \( u \) and \( d \) quarks while the \( f_0(1500) \) is compatible with the ground state scalar glueball expected around 1500 MeV. This hypothesis includes the prediction of a further scalar state, the \( f_0' (1500-1800) \), mainly composed by \( s \) quarks. This state will couple strongly to \( \mathrm{KK} \) and its discovery is essential to support the \( f_0(1500) \) glueball nature.

In order to investigate the spin of the 1750 MeV region, the angular distribution of the two \( K^0_S \)'s in the two-photon center of mass is studied. The polar angle distribution is compared in Fig. 5 with the Monte Carlo predictions for the spin two helicity-zero (\( J=2, \lambda=0 \)), spin two helicity-two (\( J=2, \lambda=2 \)) and spin zero (\( J=0 \)) cases. The Monte Carlo distributions are normalised to the same number of events as in the data and no background subtraction is done. The \( \chi^2 \) values are 50, 26 and 7 for nine degrees of freedom for \( J=2, \lambda=0 \), \( J=2, \lambda=2 \) and \( J=0 \) hypotheses respectively. \( J=0 \) assignment is found 3.2 times more probable than \( J=2, \lambda=2 \).

Experimental indications for a scalar state around 1750 MeV decaying into \( K^+K^- \) \([12]\) and \( \eta\eta \) \([13]\) have been recently found.

3.3. The 2230 MeV region

The BES Collaboration confirmed the previous observation by the Mark III Collaboration of a resonance, the \( \xi(2230) \) \([14]\), produced in radiative decays of the \( J/\psi \) particle. Due to its narrow width and its production in gluon rich environment, this state is considered a glueball candidate. Its mass is consistent with the lattice QCD prediction for the ground state tensor glueball.

Since gluons do not couple to photons, the two-photon width is expected to be small for a glueball. To make this statement more quantitative, a parameter called stickiness \([15]\) can be introduced for a state \( X \):

\[
S_X = N_l \frac{m_X}{k_{J/\psi \rightarrow \gamma X}} \frac{\Gamma(J/\psi \rightarrow \gamma \chi)}{\Gamma(X \rightarrow \gamma \gamma)}
\]

\[
\sim \frac{|<\chi|gg>|^2}{|<\chi|\gamma\gamma>|^2}
\]

where \( m_X \) is the mass of the state, \( k_{J/\psi \rightarrow \gamma X} \) is the energy of the photon from a radiative \( J/\psi \) decay in the \( J/\psi \) rest frame and \( l \) is the angular momentum between the two gluons. For spin two states \( l = 0 \). \( N_l \) is a normalisation factor that can be calculated assuming by definition the stickiness of the \( f_2(1270) \) tensor meson to be 1.

Using the same method adopted for the \( f_2(1270) \), a Monte Carlo simulation is used to de-
termine the detection efficiency for the $\xi(2230)$. For the simulation we use values for the mass and the width determined by combining the results by Mark III and BES. A mass resolution of $\sigma_{m} = 60$ MeV is found by fitting a Gaussian to the $K_S^0 K_S^0$ Monte Carlo spectrum. The total detection efficiency is measured to be 16.5% at $\sqrt{s} = 91$ GeV and 9.3% at $\sqrt{s} = 183$ GeV under the hypothesis of a pure helicity-two contribution. The signal region is chosen to be $\pm 2\sigma$ around the $\xi(2230)$ mass. In order to evaluate the background two sidebands of $2\sigma$ are considered. At $\sqrt{s} = 91$ GeV and at $\sqrt{s} = 183$ GeV, 6 and 2 events are found in the signal region respectively. Fitting a constant in the sideband region, the expected background are evaluated to be 4.9 and 7.9 events. Using the standard method for extracting an upper limit for a Poisson distribution with background, we determine upper limits of 7.3 and 3.6 events respectively at 95% C.L. Using the same method adopted for measuring the two-photon width of the $f_2(1525)$, an upper limit of $\Gamma_{\gamma\gamma}(\xi(2230)) \times Br(\xi(2230) \to K_S^0 K_S^0) < 3$ eV at 95% C.L. under the hypothesis of a pure helicity-two state.

Combining the results reported by BES and Mark III for the upper limit on $\Gamma(\xi \to K_S^0 K_S^0)$ and our lower limit on $\Gamma(\xi \to K_S^0 K_S^0) \times Br(\xi \to K_S^0 K_S^0)$, we obtain a lower limit on the stickiness $S_{\xi(2230)} > 33$ at 95% C.L. Errors are taken into account by a Monte Carlo calculation. This value is much larger than the values measured for all the established $qq$ states.

4. Conclusions

The reaction $e^+e^- \to e^+e^- \gamma^* \gamma^* \to e^+e^- K_S^0 K_S^0$ is studied with the L3 detector at LEP. The spectrum is dominated by the $f_2(1525)$ tensor meson. The angular distribution excludes pure helicity-zero and shows that helicity-two is largely dominant. The $\Gamma_{\gamma\gamma}(f_2) \times Br(f_2 \to KK)$ is found to be consistent with the previously published value $[1]$. Clear evidence for destructive $f_2-a_2$ interference is observed. An enhancement of about 6 standard deviations is observed around 1750 MeV. It may be due to the formation of a radial recurrence of the $f_2(1525)$ tensor meson ($J=2, \lambda = 2$) but the observed angular distribution favours the $J=0$ assignment. Therefore the enhancement may be due to the formation of the $ss$ member of the $0^{++}$ meson nonet. The latter case strongly supports the glueball nature of the $f_0(1500)$ glueball candidate. We obtain the upper limit $\Gamma_{\gamma\gamma}(\xi(2230)) \times Br(\xi(2230) \to K_S^0 K_S^0) < 3$ eV at 95% C.L. under the hypothesis of a pure helicity-two state.

Acknowledgments

I would like to express my gratitude to the two-photon physics group of the L3 collaboration in particular to M.N. Focacci-Kienzle, J.H. Field and B. Monteleoni.
