The mechanism of Hsp90-induced oligomerization of Tau

S. Weickert1,2*, M. Wawrzyniuk3,5†, L. H. John18, S. G. D. Rüdiger3,5, M. Drescher1,2§

Aggregation of the microtubule-associated protein Tau is a hallmark of Alzheimer’s disease with Tau oligomers suspected as the most toxic agent. Tau is a client of the molecular chaperone Hsp90, although it is unclear whether and how the chaperone massages the structure of intrinsically disordered Tau. Using electron paramagnetic resonance, we extract structural information from the very broad conformational ensemble of Tau: Tau in solution is highly dynamic and polymorphic, although “paper clip”-shaped by long-range contacts. Interaction with Hsp90 promotes an open Tau conformation, which we identify as the molecular basis for the formation of small Tau oligomers by exposure of the aggregation-prone repeat domain to other Tau molecules. At the same time, formation of Tau fibrils is inhibited. We therefore provide the nanometer-scale zoom into chaperoning an amyloid client, highlighting formation of oligomers as the consequence of this biologically relevant interaction.

INTRODUCTION

Tau is an intrinsically disordered protein (IDP) known to bind to and stabilize microtubules (MTs) and regulate axonal transport in its physiological function (1–3). In pathology, filamentous aggregates of Tau constitute a hallmark of neurodegenerative diseases, among them Alzheimer’s disease (AD) (4). Both MT binding and self-aggregation of Tau are mediated by the Tau repeat domain (Tau-RD) consisting of four imperfect repeats in the longest Tau isoform (Fig. 1A) (5, 6).

While Tau in solution is generally disordered and highly dynamic, long-range interactions mediate folding back of both termini onto Tau-RD, resulting in an overall “paper–clip” arrangement of monomeric Tau, which has been well established by a variety of experimental techniques such as nuclear magnetic resonance (NMR) and fluorescence resonance energy transfer (FRET) (7, 8). In filamentous aggregates of Tau, Tau-RD forms the ordered filamental core, while N- and C-terminal regions remain a disordered “fuzzy coat” (9, 10). Tau filaments exist in different morphologies with notable differences in the fold of the filamental cores, which are probably disease specific (11, 12). Although fibrils have long been considered the neurotoxic species, neuronal death appears rather to be caused by prefibrillar soluble aggregates and oligomers of Tau (13, 14), which are also considered responsible for spreading Tau pathogenicity from cell to cell in a prion-like concept (15, 16).

The molecular chaperone heat shock protein 90 (Hsp90) (17, 18) initiates proteasomal degradation (19–21) and induces oligomerization of Tau (22–24). Tau-RD is part of the Hsp90/Tau interaction interface (25). While insight into the molecular mechanism of the emergence of toxic Tau oligomers is highly relevant in the context of neuropathology, its structural principle is elusive.

The lack of a defined three-dimensional fold of IDPs like Tau makes their structural characterization challenging. Electron paramagnetic resonance (EPR) spectroscopy in combination with site-directed spin labeling has proven powerful in the investigation of IDPs and their aggregation behavior also in the presence of diverse interaction partners (26–31). EPR spectroscopy (i) provides information about the side-chain dynamics of a single residue (32). Dipolar spectroscopy, i.e., DEER (double electron-electron resonance) spectroscopy, (ii) gives access to distance information in the nanometer range between two spin labels by measuring their magnetic dipolar interaction frequency $\omega_{\text{DEER}}$ (33–35). Here, we exploit the combination of these approaches to investigating the molecular mechanism of Hsp90-induced Tau oligomerization.

RESULTS

We genetically engineered Tau derivatives containing one or two cysteines at specific sites and performed thiol-specific spin labeling (Fig. 1B). A range of biochemical and biophysical assays was used to monitor the success of the labeling reaction and the structural integrity of the protein (figs. S1 to S3 and table S1).

Next, we set out to characterize the structural properties of Tau by obtaining long-range intramolecular distance information with DEER on doubly spin-labeled Tau. Typical experimental DEER form factors for Tau are shown in Fig. 1C (full data in fig. S4) in comparison to simulated data for a hypothetical, well-defined distance. In contrast to the latter, the experimental traces for Tau showed no distinct modulations, indicating a broad distribution of spin-spin distances and thus implying a vast conformational ensemble of Tau in solution.

For these experimental DEER traces, the standard method for DEER data analysis fails, and the extraction of precise distance distributions is precluded (36, 37). First, we tested whether the experimental DEER data are in agreement with a simple random coil (RC) model (fig. S5). We chose RC model parameters as published by Rhoades and co-workers (38, 39) for assessing the results of FRET experiments on Tau. For certain spin-labeled stretches of Tau, e.g., Tau-17*-103*, the RC model agreed well with the experimental results (Fig. 1D and fig. S5), indicating an RC-like structural ensemble in the corresponding Tau segments. However, the RC model cannot describe the whole DEER dataset even taking variation of RC parameters depending on solvent quality into account [see fig. S6; (40, 41)]; For Tau-17*-291* and Tau-17*-433*, the deviation between the experiment and the RC model indicates a considerable...
contribution from Tau conformations more compact than RC (Fig. 1E and fig. S5). This is in good agreement with the well-established finding that Tau does not adopt RC conformation in solution but rather a paper clip (7, 8).

Hinderberger and co-workers (36, 37) proposed a data analysis procedure, which we adapted for analyzing the broad conformational ensemble of a large IDP like Tau. We evaluated the DEER data using the effective modulation depth $\Delta_{\text{eff}}$, which is the signal decay of the Tau conformational ensemble without or with Hsp90. (D) A random coil (RC) model is in reasonable agreement with DEER results for several labeled stretches of Tau, e.g., Tau-17*-103*. (E) Experimental results, e.g., for Tau-17*-433* suggest a considerably larger vicinity of spin labels than the RC simulation predicts, consistent with a paper-clip solution ensemble of Tau.

Fig. 2. Hsp90 promotes the formation of small oligomeric species of Tau. Dot blot summarizing the results of density gradient centrifugation and quantification (the color code represents Tau preparations as reported on top of the right graph): Pure Tau is mostly monomeric. Heparin induces formation of high–molecular weight fibrils. Hsp90 leads to an increase in small Tau oligomeric species, while formation of fibrils is prohibited. A.U., arbitrary units.
To elucidate the structural influence of Hsp90 on the Tau conformational ensemble, we performed DEER spectroscopy of doubly spin-labeled Tau. DEER traces remained modulation free upon addition of Hsp90 (Fig. S4). Thus, dynamic disorder prevails in Tau also when interacting with the chaperone (Fig. 1C). Addition of Hsp90 changed $\Delta_{\text{eff}}$ values, indicating a shift in the conformational equilibrium of Tau (Fig. 4B). A pronounced increase in the average spin-spin separation occurred for Tau-17*-291* and Tau-17*-433*. This indicates that the N terminus detaches from both Tau-RD and the C terminus and folds outward, opening up the paper clip (Fig. 5).

**Fig. 3. Oligomerization is mediated by the AD fibril core region of Tau.** Information about intermolecular Tau/Tau interactions obtained with DEER of singly spin-labeled Tau: Upon oligomerization, $\Delta_{\text{eff}}$ would increase locally where inter-Tau contacts are established. We observed very small $\Delta_{\text{eff}}$ values for all Tau derivatives in the absence of Hsp90 (Fig. 3), indicating only minor subpopulations of oligomeric Tau species. Addition of Hsp90 leads to a considerable increase in $\Delta_{\text{eff}}$ for Tau-322* and Tau-354*, depicted as difference values $\Delta\Delta_{\text{eff}}$. This suggests that the oligomerization interface is located in Tau-RD and specifically in R3/R4. Notably, Tau oligomerization initiates in the same Tau region responsible for AD fibril formation and Hsp90 binding (11, 25). This is remarkable, as it suggests that the same stretch of Tau mediating fibril formation (25) is addressed by Hsp90 to promote the formation of oligomers.

The dynamic properties of Tau in solution and with Hsp90 are reported by EPR spectra of spin-labeled Tau side chains. In general, we observed rather fast rotational dynamics with rotational correlation times $\tau_{\text{corr}}$ around 1 ns (Fig. 4A). This is in accordance with Tau presiding in a largely unstructured state with a broad conformational ensemble and a high degree of dynamical disorder (26). Addition of Hsp90 induced only subtle changes in the spectra (fig. S9), indicating that dynamic disorder in Tau persists also when bound. The generally still fast dynamics in the Tau spectra hints toward a transient nature of the Tau/Hsp90 complex, as only a small portion of spin-labeled Tau might be motionally restricted by intermolecular contacts, while other Tau molecules retain unrestricted rotational diffusion. We determined the half lifetime of the Tau/Hsp90 complex by quartz crystal microbalance (QCM) affinity measurements at ~10 s, which is typical for transient protein-protein interactions (fig. S10 and table S2) (44). The Tau/Hsp90 complex appears to be characterized by transient interactions between individual residues, involving a structural multiplicity of Tau.

We observed local restrictions of the reorientational mobility for spin-labeled side chains Tau-291* and Tau-322* in the presence of Hsp90. Both residues are located in Tau-RD, which has been identified as the Hsp90-binding region before (25). Thus, the altered dynamics are attributed to direct Tau/Hsp90 interaction, while also oligomer formation might restrict side chain dynamics of Tau-322*.

Spin label mobilities increased in Tau-17* and Tau-103* upon addition of Hsp90, indicating that these side chains gain a larger conformational space. Thus, one might speculate that the N terminus detaches from Tau-RD upon binding of Hsp90, opening up the paper-clip fold.
ΔΔeff values suggested a slight stretching of N-terminal Tau between Tau-17*-103* and of Tau-RD in the region between Tau-291*-322* in R2/R3, while the overall dimension of Tau-RD between Tau-244*-354* remained unchanged. While individual repeat sequences, e.g., R2/R3 expanded while accommodating Hsp90, there seems to be considerable flexibility in the remaining Tau-RD for preserving its overall dimension. A similar structural reorganization of Tau toward an open conformation was reported upon binding to tubulin, where stretches between individual repeats expanded, while the overall dimension of Tau-RD remained unaffected (38). Our results

Fig. 4. EPR of singly and doubly spin-labeled Tau derivatives gives access to Tau side-chain dynamics and intramolecular distance information. (A) Local side-chain dynamics accessed by cw EPR of 28 μM singly spin-labeled Tau derivatives: Rotational correlation times tcorr determined in the absence (dark gray) and presence (light gray) of 56 μM Hsp90 and respective changes Δtcorr (purple/pink) are shown. Arrows indicate a decrease (pink) or increase (purple) in side-chain mobility at the respective site. (B) Intramolecular distance information obtained by DEER spectroscopy with doubly spin-labeled Tau derivatives: Effective modulation depths Δeff determined in the absence (dark gray) and presence (light gray) of Hsp90 and respective changes ΔΔeff (light/dark green) are shown. Arrows indicate a decrease (light green) or increase (dark green) in spin label separation.

Fig. 5. Binding to Hsp90 induces a conformational opening of ‘paper-clip’ Tau. A structural model of Tau in the absence (left) and presence of Hsp90 (right) can be derived from EPR data of the Tau conformational ensemble. In the absence of Hsp90, Tau adopts a paper-clip shape with both termini folded back onto Tau-RD. In the presence of Hsp90 the N terminus folds outward, thereby uncovering Tau-RD.
report the conformational basis of Tau oligomerization in the presence of Hsp90 and suggest that binding to Hsp90 opens the compact Tau solution structure, exposing Tau-RD residues and presenting them to other Tau molecules. As the Tau/Hsp90 complex is of a transient nature, oligomerization of Tau molecules may then occur via exposed Tau-RD.

**DISCUSSION**

With a combination of magnetic resonance experiments and biochemical assays, we gained detailed insight into the conformational ensemble of the IDP Tau in the presence of the molecular chaperone Hsp90. While DEER spectroscopy is routinely used to extract distance restraints in well-ordered proteins or small segments of disordered proteins, we demonstrated in the current study how DEER in combination with a pragmatic approach to data analysis can be profitably used in obtaining structural information from a highly polymorphic and dynamic conformational ensemble of a large, full-length IDP. While the structural resolution of our approach is low, it enabled us to shed light on the mechanism of the full-length Tau/ Hsp90 interaction on a molecular level.

Probing Tau conformation in solution revealed a paper-clip arrangement of the domains: Fig. 5 shows a structural model of Tau summarizing our findings. The sketch is not an accurate model of Tau structure but an attempt to unite the most relevant results of this study in one possible Tau molecule representing the whole conformational ensemble. The N-terminal domain forms long-range interactions with the aggregation-prone domain, in line with previous findings (22–24). The flexible N terminus may, therefore, preclude aberrant Tau/Tau interactions, resulting in the high solubility of the full-length protein. Tau fragments lacking the N-terminal region, and therefore exposing the aggregation-prone repeat region, feature markedly accelerated aggregation rates, such as Tau-RD (45). Tau-RD is less soluble than the full-length protein despite having a higher net charge (isoelectric point pI 9.67 for Tau-RD versus 8.24 for full length) (46, 47). Tau-RD is less soluble than the full-length protein (45, 46). Hsp90 binds to Tau-RD, consistent with previous findings by us (25). The Tau/Hsp90 complex is distinguished by transient protein-protein interactions with Tau remaining conformationally heterogeneous and dynamically disordered, which is characteristic for "fuzzy" complexes (47, 48) and was also described for a ternary complex of Hsp90 with the cis–trans peptidyl-prolyl isomerase (PPlase) FKBP51 (FK506-binding protein of 51 kDa) and Tau complex (49). In the light of the large extension of the Tau/Hsp90 interaction interface (25), it is consistent that single residues contribute only little to the overall binding between Hsp90 and Tau, enabling a high rate of unbinding (47, 48). This is a typical way for Hsp90 to bind its client proteins (50, 51). In addition, Tau typically retains a high degree of conformational dynamics, at least for protein segments, when in complex with various interaction partners including heparin, tubulin, and MTs and in Tau fibrils (9, 26, 38, 52, 53). Binding to Hsp90 induces a conformational opening of paper clip–Tau (7, 8), leading to exposure of Tau-RD.

Hsp90 binding does not alter the global dimension of Tau-RD, similar as Tau bound to tubulin (40). Heparin, in contrast, compact Tau-RD (39, 54). This suggests that Hsp90 stabilizes Tau in a conformation different from the heparin-induced aggregation-prone one but similar to a conformation that might enable productive binding to MTs (19). It remains to be seen whether the Hsp90-bound shape may be similar to the fibril structure in AD. Hsp90-seeded oligomers exhibit an intermolecular DEER signal solely for the variants sampling the two C-terminal repeats R3 and R4 (Fig. 3) that mediate the early steps of Tau aggregation (26) and eventually constitute the core of the paired helical filament of AD (6, 11). In particular, the position 291 located within the Hsp90-binding region, but not the amyloid core, does not indicate any close Tau/Tau interaction. This hints toward a conclusion that the Tau/Hsp90 interaction promotes self-aggregation after opening the compact Tau solution structure, probably due to exposure of the aggregation-prone Tau-RD. However, the continuation to fibril formation is blocked in the presence of Hsp90, which may foster the generation of Tau oligomers. The conformational transition and opening up of Tau are therefore the structural basis for subsequent formation of deleterious oligomers in the presence of Hsp90.

**MATERIALS AND METHODS**

**Study design**

This in vitro EPR study was performed using full-length Tau in the absence and presence of Hsp90. Spin labeling sites were established before in single-molecule FRET (38, 39). Analysis of the conformational ensemble of Tau was based on EPR dipolar spectroscopy using DEER (33–35). Long-range intramolecular distance information was obtained with doubly spin-labeled Tau molecules and supported by monitoring the local side-chain dynamics of singly spin-labeled Tau. In addition, intermolecular interactions were monitored by DEER and singly spin-labeled Tau derivatives to gain insight into the oligomerization state of Tau. Biochemical assays, e.g., sucrose gradient ultracentrifugation, and QCM helped to shape and support the findings.

**Protein purification and spin labeling**

Human Hsp90b (Uniprot identifier P08238) and human Tau Isoform F (Uniprot identifier P10636-8) were prepared as described before (25, 55). Purification protocols and spin labelling procedures are detailed in the Supplementary Materials.

**EPR experiments**

Samples were prepared with deuterated sample buffer and had final Tau concentrations of 28 μM. Hsp90 was added where applicable at a concentration of 56 μM. For measurements at cryogenic temperatures upon shock freezing, 20% (v/v) [D8]glycerol was added to the samples.

All continuous wave EPR spectra were recorded at X-band frequency at 293 K on singly spin-labeled Tau derivatives with a typical sample volume of 10 μl. The spectra were analyzed using home-written MATLAB scripts. Rotational correlation times $\tau_{corr}$ were obtained using Kivelson’s equation (56).

DEER measurements were performed at Q-band frequency at 50 K with a sample volume of 12.5 μl. DEER raw data were analyzed globally using the DD (Version 7B) software package for MATLAB (57, 58). Effective modulation depths $\Delta eff$ were determined as a measure for the effective spin-spin separation as established by Hinderberger and co-workers (36, 37).

**Sucrose gradient ultracentrifugation and dot blot**

The oligomerization state of Tau samples incubated with Hsp90 or heparin for various incubation times as indicated in Fig. 2 were
resolved by ultracentrifugation on sucrose density gradients. Density gradients were divided into 12 equal fractions of increasing density and subjected to dot blot analysis using immunodetection and fluorimetric visualization.

**Quartz crystal microbalance**

The binding affinity of Tau for Hsp90 was determined by QCM experiments using a low nonspecific binding quartz crystal chip coated with recombinant Hsp90 by amine coupling. Tau was injected in duplicate in seven concentrations ranging from 1 to 80 μg/ml on the Hsp90-coated chip and an empty crystal for the reference. All experimental details, a description of the data analysis procedures, simulations, and corresponding control experiments can be found in the Supplementary Materials.

Acknowledgments: We thank S. Stoll for extensive discussion concerning DEER data analysis. We thank D. Bücker for assistance with coding. We thank E. Deuering for fruitful discussions. We thank M. Maurice for collaboration in the Initial Training Network “WntsApp” (no. 608180), supported by Marie-Curie Actions of the Seventh Framework Programme of the EU. We thank D. Proverbio and T. Aastrup for the guidance in the QCM measurements at Attana AB. We appreciate the help of L. Ferrari with density gradient analysis. We are grateful to I. Baa knaan for undying support. Funding: This project has received funding from the European Research Council (ERC) under the European Union’s Horizon 2020 research and innovation programme (Grant Agreement number: 772027 — SPICE — ERC-2017-COG). This work was supported by the Deutsche Forschungsgemeinschaft (SFB 969; project C03). S.G.D.R was further supported by the Internationale Stichting Alzheimer Onderzoek (ISAO; project “Chaperoning Tau Aggregation”; no. 14542) and a ZonMW TOP grant (“Chaperoning Axonal Transport in neurodegenerative disease”; no. 91215084). Author contributions: Conceptualization: S.W., M.W., S.G.D.R., and M.D. Methodology EPR: S.W., L.H.J., and M.W. Investigation: S.W., L.H.J., and M.W. Writing, initial draft: S.W. Writing, review and editing: S.W., L.H.J., and M.W. Resources: H. H. J. de Jongh, E. Goormaghtigh, J. A.
