We introduce a method of analysing longitudinal data in \( n \geq 1 \) variables and a population of \( K \geq 1 \) observations. Longitudinal data of each observation is exactly coded to an orbit in a two-dimensional state space \( S_n \). At each time, information of each observation is coded to a point \((x, y) \in S_n\), where \( x \) is the physical condition of the observation and \( y \) is an ordering of variables. Orbit of each observation in \( S_n \) is described by a map that dynamically rearranges order of variables at each time step, eventually placing the most stable, least frequently changing variable to the left and the most frequently changing variable to the right. By this operation, we are able to extract dynamics from data and visualise the orbit of each observation. In addition, clustering of data in the stable variable is revealed. All possible paths that any observation can take in \( S_n \) are given by a subshift of finite type (SFT). We discuss mathematical properties of the transition matrix associated to this SFT. Dynamics of the population is a nonautonomous multivalued map equivalent to a nonstationary SFT. We illustrate the method using a longitudinal data of a population of households from Agincourt, South Africa.

1. Introduction

Analysis of multivariable longitudinal data involves either statistical or nonstatistical methods. Statistical methods include multivariate Markov chain model [1], regression model [2], and mixed models [3], while some nonstatistical methods involve extraction of dynamical system using state space reconstruction technique [4] or visual methods such as motion charts [5,6] and parallel coordinate plots [7,8].

A motion chart shows additional dimensions of the data at different time points, where the size and color of the bubble (among others) are used as variables. PCP represents variables as parallel axes, where a sequence of line segments intersects each axis at a point corresponding to the observation’s value at the associated variable. Both methods aim to identify correlation among variables and identification of clusters and patterns among observations in the data. We present a novel nonstatistical method of analysis that is useful particularly for collecting information of change. State space reconstruction method mainly requires use of delay coordinates from data to come up with models for prediction. Our method does not rely on delay coordinates, and our aim is not prediction. Contrasting to motion charts, there is, in principle, no limitation to the number of variables studied in our method. Contrasting to PCP, for large \( n \) and large number of observations, orbits over our two-dimensional state space, or over time, are easily visualised.

Here we consider dynamics of multivariable longitudinal data of a population of observations by applying a swap operation on the data of each observation. We suppose that values of \( n \geq 1 \) variables are discretised to \( m > 1 \) bins so that each variable takes value from \( V = \{0, 1, \ldots, m-1\} \). For a fixed order of variables (e.g., \( v_0, v_1, \ldots, v_{n-1} \)) denote by

\[
M_{n,m} = V^n
\]

the space of all \( m \)-ary sequences of length \( n \) and element \( x \in M \) by \( x = x_0x_1 \cdots x_{n-1} \) such that \( x_i \) is the value of \( v_i \). The \( m \)-ary multivariable time series in \( n \geq 1 \) variables of an observation \( k \) is defined by

\[
X^k = \{X^k_0, X^k_1, \ldots, X^k_T\},
\]

where each \( X^k_i \in M_{n,m} \). Our method can be used for \( m \)-ary valued data, but for illustration, we use \( m = 2 \). We denote our binary multivariable longitudinal data \( D \) of a population of \( K \)
Table 1: Unfavourable = 0/favourable = 1 coding of four households to questions related to biological mother (BM), household head (HH), and death (AD).

| Time | h1  | h2  | h3  | h4  |
|------|-----|-----|-----|-----|
| 0    | 0,1,1 | 0,1,1 | 0,0,1 | 0,1,1 |
| 1    | 1,1,0 | 0,0,1 | 0,0,1 | 1,0,1 |
| 2    | 0,1,1 | 1,1,1 | 1,0,1 | 1,1,1 |
| 3    | 0,1,1 | 1,0,0 | 0,0,0 | 0,0,1 |
| 4    | 0,1,1 | 0,1,0 | 0,0,1 | 0,1,1 |
| 5    | 0,1,1 | 0,1,0 | 0,0,1 | 1,0,1 |
| 6    | 1,1,1 | 0,0,0 | 1,0,1 | 0,0,1 |

observations by the set of binary multivariable time series of observations

\[ D = \{ X^1, X^2, \ldots, X^K \}. \quad (3) \]

In the general analysis of longitudinal data we see no recognition that data is taken with a purpose. Here we suppose that the value of a binary variable is either favourable or unfavourable to a given purpose. Suppose we would like to investigate the effect of change of households variables, namely, biological mother (BM), household head (HH), and adult death (AD), to a child’s educational progress. Consider \( n = 3 \) binary questions

\[ Q_0: \text{Is the biological mother present? (BM)} \]
\[ Q_1: \text{Is the household headed by a minor? (HH)} \]
\[ Q_2: \text{Is there an adult death in the household? (AD)} \]

and suppose that answers are coded either favourable = 1 or unfavourable = 0 to our purpose. It is a reasonable hypothesis that the answer “yes” to \( Q_0 \) is favourable to child education, while “yes” to \( Q_1 \) and \( Q_2 \) is unfavourable. Table 1 shows coded data of 4 subjects (households) over 7 time steps. Using parallel coordinate plots (PCP), Figure 1(a) shows the answer of each subject at \( t = 0 \). To illustrate the answer for all time \( t \) using PCP, the evolution of line segments, with time, will form surfaces that obscure each other. Figure 1(b) shows the Bratelli diagram \([9, 10]\) of transition of answers from time \( t \) to \( t + 1 \), to variable order BM, HH, and AD. Transitions per time interval can be associated with a state transition matrix, where states are analysed on the space

\[ M_3 = \{ 000, 001, 010, 011, 100, 101, 110, 111 \}. \quad (5) \]

This can be used to generate probability matrices for Markov models \([11, 12]\).

Observe that, for question regarding \( Q_1 \) (HH), household \( h1 \) has constant favourable answer, while \( h3 \) has constant unfavourable answer. On the other hand, \( h4 \) has constant favourable answer to \( Q_3 \) (AD). Our aim is to extract clusters associated with stable variables. Underlying our method is our belief that the set of physical variables in which an observation spends the most time in is important (e.g., HH = 1 for \( h1 \), HH = 0 for \( h3 \), and AD = 1 for \( h4 \)) and that among the physical variables themselves the variables that are most often experienced (most probable) by the observations are important. We elegantly expose both most probable variable and value of variable, by a simple process of dynamically reordering variables.

There is no a priori indication of any absolute dynamics in data and here it is deterministically imposed. Because longitudinal data is fundamentally defined by change (if nothing changes, cross-sectional data is sufficient), frequency of answer change of variables then becomes a property of interest. A deterministic operation is applied to the multivariable data of each observation at each time step, dynamically reordering position of variables (and their corresponding values) by their stability; that is, the most stable is eventually positioned to the left, and the most frequently changing one is positioned to the right. All possible orders of variables are considered. From this, we introduce the significance state (order of variables) and fitness state (associated values with variables) of an observation. It is in a chosen ordering that the notion of fitness takes an objective and consistent meaning. The idea of fitness and significance is new in literature. The \( n \)-dimensional longitudinal data of an observation is represented as a 2-dimensional orbit in fitness-significance space. Permutation of \( n \) elements produces \( n! \) points. Orbits in \( S_n \) sufficiently encode the longitudinal data of each observation. Analysis of orbits at the individual and population levels in this space can then follow.

This paper is organized as follows. In Section 2, we present the method of constructing orbits from multivariable longitudinal data. A detailed theory of the reordering operation applied to data is presented. In Section 3, a deterministic equation of motion that generates all observed orbits, as well as other possible orbits, is presented. In Section 4 we discuss transitions that occur in data. This is captured by a nonstationary SFT. We also discuss dynamics at the population level. An illustration of the method is presented in Section 5. We give concluding remarks in Section 6.

2. Background and Preliminaries: Method of Orbits

We suppose that longitudinal data is gathered by first specifying a purpose and then choosing questions that are of interest to purpose. The questionnaire may be designed to a purpose posed in the form “to investigate the effect of the \( n \) variables \( v_0, v_2, \ldots, v_{n-1} \) on \( Z \).” Here we will only consider binary-valued questions with responses hypothesized as either favourable or unfavourable to the purpose. A favourable answer is coded 1 and 0 otherwise. Our longitudinal data is the response to a set of \( n \geq 1 \) questions (associated with variables) surveyed from a population \( P \) composed of \( K \geq 1 \) observations over \( T \) periods.

Denote the questionnaire by

\[ Q = \{ Q_0, Q_1, \ldots, Q_{n-1} \}, \quad (6) \]

the set containing \( n \) questions. Let \( I_n = \{ 0, 1, \ldots, n - 1 \} \) be an index set of \( n \) elements, and let time \( t = 0, 1, \ldots, T \).
Figure 1: Visual display of data of four subjects in Table 1 (a) at \( t = 0 \) using PCP, where each parallel line is composed of answers 0 and 1 and (b) for all time \( t = 0, 1, \ldots, 6 \) using a Bratelli diagram, where each parallel line is composed of states from \( M_3 = \{0, 1\}^3 \), the space of binary sequences of length 3.

Table 2: Data of observation \( k \) (column 2), with questions reordered at \( t = 0 \) and \( t = 1 \).

| Observation \( k \) | Coded answers to \( Q = \{Q_0, Q_1, Q_2\} \) | Concatenation of answers to \( Q_k \) | Concatenation of indices of \( Q_k \) |
|------------------|---------------------------------|-------------------------------|---------------------------------|
| \( t = 0 \)      | \( [0, 1, 0] \)                | 100                           | 102                             |
| 1                | \( [0, 0, 1] \)                | 010                           | 021                             |

Let \( j, i_j \in I_n \) and let \( x_j \in \{0, 1\} \). For each observation \( k = 1, 2, \ldots, K \), denote a reordering of questions in \( Q \) at time \( t \) by

\[
Q^k_t = \{Q_{i_1}, Q_{i_2}, \ldots, Q_{i_{n-1}}\}_t
\]

the concatenation of answers to \( Q^k_t \) by

\[
x^k_t = x^k_{0t} \cdot x^k_{1t} \cdots x^k_{(n-1)t} = (x^k_{j t})_{j=0}^{n-1}
\]

and the concatenation of question indices of \( Q^k_t \) by

\[
y^k_t = y^k_{0t} \cdot y^k_{1t} \cdots y^k_{(n-1)t} = (y^k_{j t})_{j=0}^{n-1}
\]

Example 1. Coded data of observation \( k \) for \( t = 0 \) and \( t = 1 \) is shown in column 2 of Table 2. Suppose we (arbitrarily) reorder the questions at \( t = 0 \) to \( \{Q_1, Q_0, Q_2\} \). Then \( x^0_0 = 010 \) and \( y^0_0 = 102 \). Similarly, if \( Q^k_t = \{Q_2, Q_0, Q_1\} \), we have \( x^k_0 = 001 \) and \( y^k_0 = 201 \). As we are merely rewriting entries from the original data, all information is preserved.

2.1. Fitness and Significance States. Consider questions in (4) and assign index \( i \) to \( Q_i \) (\( i = 0, 1, 2 \)). Suppose we give more weight (significance) to \( Q_0 \) and do this by positioning 0 in the left-end of question order, say, \( Q_0, Q_1, Q_2 \), denoted by 012 (or \( Q_0, Q_2, Q_1 = 021 \)). As in numbers or decimals, our weighting places the most significant number at the left-end position. All possible (concatenated) answers to 012 are given by

\[001, 000, 010, 111, 110, 101, 100, 011.\]  

Since 000 has all unfavourable answers we say that it is the least fit answer, while 111 is the fittest. Note that there are states with the same number of favourable values, for example, 001, 100, and 010. By a suitable weighting of questions, we show below that the lexicographic ordering of answers in (10) is an appropriate ordering of fitness.

Table 3 illustrates concatenated coded answers to question order 012 of three observations from a population. To \( Q_0 \), observation \( k \) has constant answer 0 while \( k' \) has constant answer 1.

Suppose we arrange answers in (10) lexicographically along an \( x \)-axis. Then for question order 012, a one-dimensional dynamics on the \( x \)-axis composed of the eight states arises. Answers of \( k \) and \( k' \) to \( Q_0 \) seldom change (i.e., they are both constant in \( Q_0 \)) so the two households \( k \) and \( k' \) stay in the regions \( 0 \ast \ast \ast \) and \( 1 \ast \ast \ast \ast \) of the \( x \)-axis, respectively. Recall that \( Q_0 \) is the question associated with the significant (left) position of the question order so fitness is biased towards the left position. We can then write \( x = 0 \ast \ast \ast < x' = 1 \ast \ast \ast \) because the significant variable \( Q_0 \) is unfavourable in \( x \) and favourable in \( x' \). This holds true even if \( x \) has the same, or more, favourable values as \( x' \). This argument can be extended to any two elements \( x, x' \in M_n \) with the same first \( \ell \) entries.

In general, not all observations may be stable in the same variable; for example, \( k'' \) in Table 3 is constant in \( Q_0 \), not
Moreover, stability of an observation may change in time; it may be stable in variable \( i \) over one time interval and then stable in variable \( i' \) over another time interval. We will not study orbits in a fixed question order alone. We construct a \( y \)-axis with states corresponding to question orders. The order of questions per observation becomes a new variable.

**Definition 2.** Given \( n \geq 1 \) and \( Q_k \), the fitness state and significance state of observation \( k \) at time \( t \) are the sequences

\[
x^k_t = (x^k_{jt})_{j=0}^{n-1}, \quad y^k_t = (y^k_{jt})_{j=0}^{n-1}
\]

respectively. The set of fitness states of length \( n \) is called the fitness space of \( n \) variables defined by

\[
X_n := \left\{ (x^i_j)_{j=0}^{n-1} : x^i_j \in [0, 1] \right\}
\]

and the set of significance states of length \( n \) is called the significance space of \( n \) variables defined by

\[
Y_n := \left\{ (i^j_{jt})_{j=0}^{n-1} : i^j_{jt} \in I_n, j \text{ distinct} \right\}.
\]

Elements of both \( X_n \) and \( Y_n \) are arranged according to the lexicographic ordering (<) of sequences of length \( n \).

**Definition 3.** The space

\[
S_n = \left\{ p = (x, y) : x \in X_n, y \in Y_n \right\}
\]

is called the change space for \( n \) variables.

Given \( n \), we have the cardinalities \( |X_n| = 2^n \), \( |Y_n| = n! \), and \( |S_n| = N = 2^n n! \). A way of labeling state \( s_j \in S_n \) via the map

\[
\psi : S_n \rightarrow \{1, 2, \ldots, N\}, \quad s_j \mapsto \psi(s_j) = j,
\]

\[
j = 1, 2, \ldots, N.
\]

For convenience, we label states in \( S_n \) from left to right, and from top to bottom. If \( s_j = (x, y) \) and \( \psi(s_j) = j \), we will refer to state \( s_j \) as state \( j \) and write \( j = (x, y) \).

**Remark 4.** In general, for multivariate data in \( n \) variables, with all variables \( m \)-ary valued, the space \( S_{mn} \) is composed of \( m^n \times n! \) states.

### 2.2. The Method of Orbits

We define the dynamics of observations taken from a survey of \( n \geq 1 \) questions. Let \( \mathcal{I}_n \) be the set of nonnegative integers, let \( \mathcal{C}_n = \mathcal{P}(\mathcal{I}_n) \) be the power set of \( \mathcal{I}_n \), and let \( x^*_j \) be such that

\[
x^*_j = \begin{cases} 1 & \text{if } x_j = 0 \\ 0 & \text{if } x_j = 1. \end{cases}
\]

**Definition 5.** Let \( \Delta \in \mathcal{C}_n \) and let \( j \in \Delta \).

(a) The map \( \Phi_\Delta : S_n \rightarrow S_n \) is defined by

\[
\Phi_\Delta \left( x_0 x_1 \cdots x_{n-1}, y \right) = \left( x_0 x_1 \cdots x_{n-1}, y \right).
\]

(b) The map \( \phi_j : S_n \rightarrow S_n \) is defined by

\[
\phi_j \left( x_0 x_1 \cdots x_{n-1}, i_0 i_1 \cdots i_{j-1} i_{j+1} \cdots i_{n-1} \right)
= \left( x_0 x_1 \cdots x_{j-1} x_{j+1} \cdots x_{n-1}, i_0 i_1 \cdots i_{j-1} i_{j+1} \cdots i_{n-1} \right).
\]

Let \( j, j' \in \Delta \). Then \( x_j \) and \( x_{j'} \) both change values under \( \Phi_\Delta \). If \( j < j' \), then \( \phi_j \) is first applied to \( j' \); that is,

\[
\phi_j \left( x_0 x_1 \cdots x_{j-1} x_{j} x_{j+1} \cdots x_{n-1}, i_0 i_1 \cdots i_{j-1} i_{j+1} \cdots i_{n-1} \right)
= \left( x_0 x_1 \cdots x_{j-1} x_{j+1} \cdots x_{n-1}, i_0 i_1 \cdots i_{j-1} i_{j+1} \cdots i_{n-1} \right).
\]

**Definition 6.** Let \( i_j \in \mathcal{I}_n \). Consider questionnaire \( Q \) with \( Q_{ij} \in Q \). For each observation \( k \), let \( f^k_{ij} \) be the frequency of change in answer value of \( Q_{ij} \) over the observation period. Suppose

\[
0 < f^k_{ij} < f^k_{i_1 j_1} < \cdots < f^k_{i_j j} < \cdots < f^k_{i_n j_n}.
\]

Inequality (20) is called the observation frequency relation and question order \( y^k_0 = i_0 i_1 \cdots i_{n-1} \) is the initial significance state of observation \( k \). If \( f^k_{ij} = f^k_{i_1 j_1} \) and \( f^k_{ij} < f^k_{i_1 j_1} \) at the population level, then choose question order \( i_j j_1 \). If \( f^k_{ij} = f^k_{i_1 j_1} \), then choose question order as in the questionnaire (6). The initial fitness state \( x^k_0 = x_0 x_1 \cdots x_{n-1} \) is such that \( x_j \) is the value of \( i_j \) in \( y^k_0 \). The initial state of \( k \) is the ordered pair \( p^k_0 = (x^k_0, y^k_0) \).

By choosing the initial significance \( y^k_0 \) given in Definition 6, we start the orbit in its most-likely significance state. This facilitates convergence to clusters (where they exist) and is useful for short data sets. Other strategies (e.g., using order of (6) or random choice) will nonetheless converge to question order according to (20).

**Remark 7.** Longitudinal data is only of interest where change occurs; else cross-sectional surveys are adequate. We are interested in longitudinal data that give nontrivial information of change about the population; that is, \( f^k_{ij} \neq 0 \). Otherwise, question \( i_j \) may be deleted as any such property becomes an identifier of subpopulations of possible interest for analysis in its own right.

**Definition 8.** For each observation \( k \), define the change set at time \( t \) by

\[
\Delta^k_t = \left\{ j : Q_{ij} \in Q^k \text{ changes answer value at time } t+1 \right\}.
\]
Let \( p_0^k = (y_0^k, x_0^k) \) be the initial state of \( k \). Denote by \( p_t^k = (x_t^k, y_t^k) \) the state of \( k \) at time \( t \geq 0 \). The change map \( \varphi : (N_n, C_n, S_n) \to S_n \) is such that

\[
\varphi \left( t, \Delta^k_t, p_t^k \right) := \varphi_{|\Delta_t^k} \left( p_t^k \right) = \left( \phi_y \circ \phi_{x^k} \right) \left( p_t^k \right) = p_{t+1}^k.
\]

The set \( \Delta^k_t \in C_n \) is given by the longitudinal data for each \( t \geq 0 \) and is a useful ordered listing of questions that change answer values from time \( t \) to \( t + 1 \). For each \( k \), the nonautonomous map \( \varphi_{|\Delta_t^k} \) defines an evolutionary process that displaces the most frequently (resp., slowly) changing answers and corresponding questions to the right (resp., left).

**Definition 9.** Given initial state \( p_0^k \) of \( k \), define the state of \( k \) at time \( t \geq 1 \) by

\[
p_t = \varphi_{|\Delta_{t-1}^k} \left( \cdots \left( \varphi_{|\Delta_0^k} \left( p_0^k \right) \right) \right).
\]

The forward orbit of \( k \) under \( \varphi \) is defined by

\[
O^k_k = \{ p_t \}_{t \in \mathbb{N}_n}.
\]

2.3. Algorithm for Building the Orbit of an Observation in \( S_n \).

We give a simple algorithm to determine the states \( p_t^k \) that comprise the orbit of an observation \( k \) from longitudinal data.

**Step 1.** Determine initial question order \( y_0^k \) and initial state \( p_0^k = (x_0^k, y_0^k) \) of \( k \) and plot \( p_0^k \) in \( S_n \).

**Step 2.** Identify from the data of \( k \) the question that changes answer at time \( t = 1 \), say \( Q_{i_1} \). Swap both \( i_j \) (in \( y_0^k \)) and corresponding answer \( x_{i_j} \) (in \( x_0^k \)) to the right of \( y_0^k \) and \( x_0^k \), respectively, and change \( x_j \) to \( x_j^* \), where \( x_j^* = 0 \) if \( x_j = 1 \) and 0 otherwise. This new question order and answer order give the next state \( p_1^k = (x_1^k, y_1^k) \) of \( k \). Suppose both \( Q_{i_j} \) and \( Q_{i_{j+1}} \) change answers at \( t = 1 \). If \( j < j \), then sequentially swap to the right \( i_j \) and \( i_{j+1} \) (resp., \( x_j \) and \( x_{j+1} \)) of the question order (resp., answer order), starting with \( i_j \) (resp., \( x_j \)). Change \( x_j \) to \( x_j^* \) and \( x_{j+1} \) to \( x_{j+1}^* \). Plot the point \( p_1^k \) in \( S_n \) and directed edge from \( p_0^k \) to \( p_1^k \).

**Step 3.** Repeat Step 2, updating state \( p_{t-1}^k \to p_t^k \) and \( t \to t + 1 \) for time \( t = 1, 2, \ldots, T - 1 \).

Visualization and analysis of orbits of observations in \( S_n \) allow capturing information of change in longitudinal data. We illustrate in Figure 2 an orbit in \( S_n \). The useful distance on \( S_n \) is given by the discrete metric; that is, \( d(p, p') = 1 \) if \( p \neq p' \) and zero otherwise. The visualized distance between points in \( S_n \) has no interpretation so we may represent \( S_n \) by a regularly spaced point.

**Figure 2:** State transitions of observation \( k \) (from Table 4) in \( S_n \).

**Table 4: States of observation \( k \).**

| Unit \( k \) | Coded answers to \( Q = \{Q_{i_1}, Q_{i_2}, Q_{i_3}\} \) | Fitness \( y_i \) | Significance \( y_i^* \) | \( \Delta_i \) |
|---|---|---|---|---|
| 0 | \{1, 0, 0\} | 010 | 201 | (1, 2) |
| 1 | \{0, 1, 0\} | 010 | 210 | (1) |
| 2 | \{0, 0, 0\} | 000 | 201 | (0, 1, 2) |
| 3 | \{1, 1, 1\} | 111 | 102 | |

Remark 10. The set of all orderings of variables is captured in \( S_n \). For fixed question order and \( x, x' \in X_n \), \( x < x' \) means that fitness state \( x' \) is fitter than \( x \). Each level in the significance axis is question order under frequency ordering. The significance axis informs us which variables are weighted most strongly at each time, where significance is ordered from left to right. Clearly, reordering of variables is one among many families of operations; for example, swapping can be done by swapping changing variable to the left end. This operation however does not reveal clusters.

2.4. Transitions in \( S_n \). We now analyze possible state transitions which an observation \( k \) can take in \( S_n \).

**Definition 11.** Let \( p = (x, y) \) and \( p' = (x', y') \) be in \( S_n \), and let \( \Delta \in C_n \).

(a) Suppose \( \Delta = \{[\Delta] \} \) is such that \( \varphi_{[\Delta]}(p) = p' \). Then there is a **transformation** from \( p \) to \( p' \) under \( \Delta \), defined by \( p \xrightarrow{[\Delta]} p' \).

(b) Suppose \( p \xrightarrow{[\Delta]} p' \). If \( y = y' \) and \( x \neq x' \), then there is a **horizontal transition** from \( p \) to \( p' \). If \( x = x' \) and \( y \neq y' \), then there is a **vertical transition** from \( p \) to \( p' \).

(c) Suppose \( p \xrightarrow{[\Delta]} p' \). If, in addition, \( \Delta \) is such that \( p' \xrightarrow{[\Delta]} p \), then the transition from \( p \) to \( p' \) is **reversible**, and one writes \( p \xleftarrow{[\Delta]} p' \).

We have self-transitions if \( \Delta = \emptyset \) (no change), the empty set. In general, horizontal transitions denote change in
Proof. (a) Let $x = x_0 x_1 \cdots x_{n-1}$ be the fitness state of $p \in S_n$. The image of $x$ under both maps $\phi_\Delta$ and $\phi_J$ is unique so $p^\dagger$ is a manipulation of the right-most variable, while vertical transitions denote change in the last two variables.

Let $p, p' \in S_n$. Given an observation $k$, if $p^k \in p$ and $p_{t+1}^k \in p'$, then there is $\Delta_j \in \mathcal{C}_n$ such that $p \rightarrow \Delta \rightarrow p'$. We use the symbol "c" to denote that there may be other observations in $p$ or $p'$ at times $t$ and $t+1$, respectively. State transitions of observation $k$ in $S_n$ are visualised as a sequence of directed edges.

Example 12. Consider data of observation $k$ in column 2 of Table 4. The asterisks denote changing answers in the next time step. The frequencies of change are $f^k_0 = 2$, $f^k_1 = 3$, and $f^k_2 = 1$, so the initial question order of $k$ is $y_0^k = 201$. And initial fitness state is $x^0 = 010$ (Definition 6). At $t = 0$, we apply $\psi_{\Delta_0^k}$ to initial state $p_0^k = (010, 201)$. Questions $i_1 = 0$ and $i_2 = 1$ in $Q^k$ change answers in the next time step so $\Delta_0^k = [0, 0]$ (not $[0, 1]$). Applying $\psi_{\Delta_0^k}$ to $(010, 201)$ changes $x_{i_1} = 1$ and $x_{i_2} = 0$, respectively. Next, $\phi_J$ is first applied to both $x^*_{i_1}$ and $i_{i_2}$ by moving each to the right (they are already rightmost), followed by moving $x^*_{i_1}$ and $i_{i_2}$ to the right end. Hence, we have $(x, y)^k_1 = (010, 210)$. For $t = 1$ and $t = 2$, verify that $\Delta_1^k = [0, 1, 2]$ and $\Delta_2^k = [0, 1, 2]$, respectively. At each time $t$ the bold numbers in the significance column are the question indices in $Q$ that change answers at $t + 1$. The orbit of $k$ in $S_n$ is shown in Figure 2. The vertical transition from state II to 3 denotes two changing answers, while a transition from state 9 to 32 denotes three changing answers.

Example 13. Figures 3(a) and 3(b) illustrate the associated orbits in $S_4$ of the four households given in Table 1. Observe that orbit of h3 stays strictly on the left half of $S_n$, particularly in subset where $Q_1 (HH) = 0$, while h1 and h4 stay in the right half subset, where $Q_1 (HH) = 1$ and $Q_2 (AD) = 1$, respectively.

Definition 14. Let $\Delta \in \mathcal{C}_n$ and let $j \in \Delta$. The return map $\tilde{\psi}_{\Delta|\Delta} : S_n \rightarrow S_n$ is such that

$$
\tilde{\psi}_{\Delta|\Delta}(x_0 x_1 \cdots x_{n-1} i_0 i_1 \cdots i_{n-1}) = (x_0 x_1 \cdots x_{j-1} x^*_{j-1} x_{j+1} \cdots x_{n-2}, i_0 i_1 \cdots i_{j-1} i_{j+1} \cdots i_{n-2}).
$$

That is, $\tilde{\psi}_{\Delta|\Delta}$ first inserts $x_{j-1}$ and $i_{j-1}$ to the position, where $x_j$ and $i_j$ are located, followed by changing $x_{n-1}$ to the new value $x^*_j$. If $j, j' \in \Delta$ and $j < j'$ then $\tilde{\psi}_{\Delta|\Delta}$ is first applied to $x_j$ and $i_j$.

Trivially, for any $n \geq 1, p \in S_n$, and $\Delta \in \mathcal{C}_n$,

$$
\tilde{\psi}_{\Delta|\Delta}(\psi_{\Delta|\Delta}(p)) = \psi_{\Delta|\Delta}(\tilde{\psi}_{\Delta|\Delta}(p)) = p.
$$

Theorem 15. Let $p \in S_n$. Define the image set and preimage set of $p$ over $\mathcal{C}_n$ by

$$
\mathcal{J}_p = \bigcup_{\Delta \in \mathcal{C}_n} \{ p' \in S_n : \psi_{\Delta|\Delta}(p) = p' \},
$$

$$
\overline{\mathcal{J}}_p = \bigcup_{\Delta \in \mathcal{C}_n} \{ \tilde{p} \in S_n : \tilde{\psi}_{\Delta|\Delta}(\tilde{p}) = p \},
$$

respectively. For each $\Delta \in \mathcal{C}_n$,

(a) there exists a unique $p' \in S_n$ such that $\psi_{\Delta|\Delta}(p) = p'$.
Moreover, $|\mathcal{J}_p| = 2^n$;
(b) there exists a unique $\tilde{p} \in S_n$ such that $\tilde{\psi}_{\Delta|\Delta}(\tilde{p}) = p$.
Moreover, $|\overline{\mathcal{J}}_p| = 2^n$.

Proof. (a) Let $x = x_0 x_1 \cdots x_{n-1}$ be the fitness state of $p \in S_n$. The image of $x$ under both maps $\phi_\Delta$ and $\phi_J$ is unique so $p'$ is
unique. Note that $|\mathcal{C}_n| = 2^n$ and the set of images of $x$ under $\varphi_{\Delta}(\cdot)$, $\Delta \in \mathcal{C}_n$, is the set of distinct binary numbers of length $n$, which can be associated with $2^n$ distinct states in $S_n$. This is a bijection between elements of $\mathcal{C}_n$ and the binary numbers of length $n$, so $|\mathcal{F}_p| = 2^n$.

(b) For $\Delta \in \mathcal{C}_n$, choose $\tilde{\varphi} = \varphi_{\Delta}(\cdot)$, where $\tilde{\varphi}_{\Delta}$ is the return map. The proofs of the uniqueness of $\tilde{\varphi}$ and the cardinality of $\mathcal{F}_p$ follow a similar argument as in (a).

**Theorem 16.** Let $n \geq 2$ and $p \in S_n$. If $\Delta = [n-m, n-1]$, then $\varphi_{\Delta}^m(p) = p$ for $m = 2, 3, \ldots, n$.

**Proof.** Fix $n$ and $m$, where $2 \leq m \leq n$. Let $a = x_0x_1 \cdots x_{(n-m-1)}$ and $b = i_o i_1 \cdots i_{(n-m-1)}$ be sequences of length $(n-m)$ so that

$$\begin{align*}
p &= (ax_{(n-m)}x_{(n-m+1)} \cdots x_{(n-2)}x_{(n-1)}) , \\
b &= (bi_{(n-m)}i_{(n-m+1)} \cdots i_{(n-2)}i_{(n-1)}) .
\end{align*}$$

(28)

Let $\Delta = [n-m, n-1]$. Observe that, for any integer $\ell > 0$, $a$ and $b$ are fixed under $\varphi_{\Delta}$. Now

$$\begin{align*}
\varphi_{\Delta}(p) &= (ax_{(n-m+1)} \cdots x_{(n-2)}x_{(n-1)}x_{(n-m)}) , \\
bi_{(n-m)}i_{(n-m+1)} \cdots i_{(n-2)}i_{(n-1)}
\end{align*}$$

(29)

For $\ell = m - 1, \varphi_{\Delta}^{m-1}(p) = (ax_{(n-m+1)} \cdots x_{(n-2)}x_{(n-1)}x_{(n-m)} \cdots x_{(n-m-\ell)}) . b i_{(n-m)}i_{(n-m+1)} \cdots i_{(n-2)}i_{(n-1)}$. Hence, $\varphi_{\Delta}(\varphi_{\Delta}^{m-1}(p)) = \varphi_{\Delta}^m(p) = p$.  

**Corollary 17.** For any $n \geq 1$, $p \in S_n$, and $\Delta \in \{[n-1], [n-2, n-1], I_n\}$, the transition from $p$ to $p' = \varphi_{\Delta}(p)$ is reversible.

The next theorem states some nonallowable transitions in $S_n$.

**Theorem 18.** Let

$$\begin{align*}
y &= i_0 i_1 \cdots i_{n-2}i_{n-1} , \\
y' &= i_0' i_1' \cdots i_{n-2}'i_{n-1}' ,
\end{align*}$$

(30)

for $j \in I_n \setminus \{0\}$.

**Define**

$$\begin{align*}
S_y &= \{ p \in S_n : y is the significance state of p \} , \\
S_{y'} &= \{ p \in S_n : y' is the significance state of p \} , \\
S_{y''} &= \{ p \in S_n : y'' is the significance state of p \} .
\end{align*}$$

(a) Let $n \geq 2$. The only transitions in $S_y$, aside from self-transitions, are horizontal transitions. Let $n \geq 3$.

(b) There is no transition from $S_y$ to $S_{y'}$.

(c) There is no transition between $S_y$ and $S_{y''}$.

**Proof.** (a) It is easy to show that any transition between distinct points with the same significance state is under $\Delta = [n-1]$. In particular, horizontal transitions are between pairs $p = (x_p, y)$ and $\tilde{p} = (x_{\tilde{p}}, y)$, where $x_p = x_0x_1 \cdots x_{(n-2)}x_{(n-1)}$ and $x_{\tilde{p}} = x_0x_1 \cdots x_{(n-2)}x_{(n-1)}$.

(b) Let $p \in S_y$. The sets $\Delta = I_n$ and $\Delta = [0, 1, \ldots, n-2]$ are the only elements of $\mathcal{C}_n$ such that $i_{n-1}$ is moved to the leftmost position of the question order of $\varphi_{\Delta}(p)$, in which case case question order must be $i_{n-1}i_{n-2} \cdots i_0$, different from $y$.

(c) As in (b), $\Delta = \emptyset$ and $\Delta = [n-1]$ are the only elements of $\mathcal{C}_n$ such that $i_{n-1}$ remains in its position under $\varphi_{\Delta}$. The rest of the proof follows a similar argument as in (b).

2.5. Local Dynamics in $S_n$. Consider the subset

$$\begin{align*}
\mathcal{L}_m \subset \Delta_n = \{(c_0c_1 \cdots c_{(n-m-1)}x_{(n-m)} \cdots x_{(n-1)} , \\
e_0 e_1 \cdots e_{n-m-1} i_{n-m} \cdots i_{n-1) , \\
\cdots, c_j, \ell_j constant, x_j \in [0, 1], i_j \in I_n\} ,
\end{align*}$$

(32)

where $n - m$ answers are constant. Since $|\mathcal{L}_m| = m!2^{n-m}$ states and $|\Delta_n| = n!2^n$ states, then $S_n$ is composed of $2^{n-m}n!/m!$ subsets of the form $\mathcal{L}_m$. For $n-1$ constant answers (i.e., $m = 1$), denote by $\mathcal{L}_{n-1}^{(c,\ell)}$ the subset of $S_n$, where question $\ell$ has constant answer $c$. Then any $p \in \mathcal{L}_{n-1}^{(c,\ell)}$ is given by $p = (cx_1x_2 \cdots x_{(n-2)}i_{(n-1)}i_{n-1} \cdots i_1, x_j \in [0, 1], i_j \in I_n)$. Define $\mathcal{L}_{n-1}^{(c,\ell)}$ by

$$\mathcal{L}_{n-1}^{(c,\ell)} = \bigcup_{\ell \in I_n} \mathcal{L}_{n-1}^{(c,\ell)} .$$

(33)

Using (33), we can express $S_n$ as

$$\begin{align*}
\Delta_n = \mathcal{L}_{n-1}^{(0)} \cup \mathcal{L}_{n-1}^{(1)} , \\
S_n = \Delta_n .
\end{align*}$$

(34)
We now define the set (as in $\mathcal{C}_n$) associated with transitions between points in $\mathcal{L}_m$, where $m < n$. Recall from Theorem 15 that transitions in $\mathcal{S}_n$ are under elements $\Delta$ of the set $\mathcal{P}(I_0) = \mathcal{C}_n$. For $m = 1$, there are $n - 1$ constant answer values so transitions in $\mathcal{L}_1$ are under elements of the set

$$\mathcal{D}_1^{(n)} = \mathcal{P}(\{n - 1\}), \quad n \geq 1$$

$$= \{0, n - 1\}.$$  \hfill (35)

Similarly, for $n - 2$ constant answer values (i.e., $m = 2$), transitions in $\mathcal{L}_2$ are under the set

$$\mathcal{D}_2^{(n)} = \mathcal{P}(\{n - 2, n - 1\}), \quad n \geq 2$$

$$= \{0, n - 1\} \cup \{n - 2, n - 1\}$$ \hfill (36)

$$= \mathcal{D}_1^{(n)} \cup (\mathcal{P}(\{n - 2, n - 1\}) \setminus \mathcal{D}_1^{(n)}).$$

In general, the dynamics in $\mathcal{L}_m \subset \mathcal{S}_n$ is described by transitions under the set

$$\mathcal{D}_m^{(n)} = \mathcal{P}(\{n - m, n - m + 1, \ldots, n - 1\}), \quad n \geq m$$

$$= \mathcal{D}_{m-1}^{(n)} \cup (\mathcal{P}(\{n - m, n - m + 1, \ldots, n - 1\}) \setminus \mathcal{D}_m^{(n)}).$$  \hfill (37)

For $m = n$, we see from (37) that $\mathcal{D}_n^{(n)} = \mathcal{C}_n$, as expected. Moreover, the transitions in $\mathcal{S}_n$ are given by the transitions in $\mathcal{S}_{n-1}$, together with the additional transitions under the set difference $\mathcal{C}_n \setminus \mathcal{D}_n^{(n)}$.

Since $|\mathcal{L}_m| = |\mathcal{S}_m|$ and $|\mathcal{D}_m^{(m)}| = |\mathcal{C}_m|$ for $m \leq n$ and that there is a one-to-one correspondence between transitions in $\mathcal{L}_m$ and $\mathcal{S}_m$ (from (37)), we can write $\mathcal{L}_m = \mathcal{S}_m$.

Example 19. Figures 4(a) and 4(b) illustrate all possible transitions in $\mathcal{S}_1$ and $\mathcal{S}_2$, respectively. Consider horizontal transitions alternating between states 1 and 2. In Figure 4(a), this denotes alternating 0-1 answer to question 0. On the other hand, transitions alternating between states 1 and 2 in Figure 4(b) denote alternating 0-1 answer to question 0 with constant favourable answer to question 1. All transitions between states in the dashed boxes (containing $\mathcal{L}_1^{(c, F)}$) are under the map $\varphi_{\{1,1\}}$, where “1” refers to the index on the right end of question order $I_{01}$. In each $\mathcal{L}_1^{(c, F)}$, one answer value is constant and is positioned at the left end of the fitness state. The digraph associated with transitions in $\mathcal{S}_1$ is exactly the same as the digraph associated with transitions in each $\mathcal{L}_1^{(c, F)}$. Transitions in these subsets $\mathcal{L}_1^{(c, F)}$ are under $\varphi_{\{1\}}$.

Example 20. Figure 5 illustrates orbits in $\mathcal{S}_4$ that cluster into two. A red edge signifies a movement from right to left, a green edge a movement from left to right, and a blue edge a transition to the same state (self-transition). Instead of analysing in $\mathcal{S}_4$, we can remove $Q_3$ and consider only the three questions $Q_0$, $Q_1$, and $Q_2$ and analysing orbits in $\mathcal{S}_3$ characterised by $Q_3 = 0$ and orbits characterised by $Q_3 = 1$. Note that the frequency change of $Q_3$ here is $f_3 = 0$. 

![Figure 4](image4.png)

![Figure 5](image5.png)
3. General Equation of Motion of Dynamics in $S_n$

This section concerns properties of all possible paths in $S_n$.

Definition 21 (see [13]). Let $X$ and $Y$ be arbitrary sets. A multivalued map $F$ from $X$ to $Y$, denoted by $F : X \Rightarrow Y$, is such that $F(x)$ is assigned a set $Y_x \subset Y$ for all $x \in X$.

Consider our state space $S_n$. Denote by $\varphi_{[\Delta]} : \mathcal{S}_n \to \mathcal{S}_n$ the map in (22), where $\Delta$ is constant. Define

$$G = \{ \varphi_{[\Delta]} : \Delta \in \mathcal{C}_n \}$$

(38)

and the multivalued map $F : \mathcal{S}_n \Rightarrow \mathcal{S}_n$ by

$$F(p) = \bigcup \{ g(p) \mid g \in G \}.$$  

(39)

$|F(p)| = 2^s$ so $F$ is a 1 to $2^m$ map. Under $F$, the orbit $\{p^k\}_{k \in n}$ is such that $p^k_{n+1} \in F(p^k)$. The multivalued map $F$ can be interpreted as a digraph whose $N = n!2^m$ vertices are the points in $S_n$ and edge $p \to p'$ if $p' \in F(p)$.

Equivalently, $F$ can be defined as a square matrix of size $N$ that encodes all possible paths in $S_n$.

Definition 22. Let $V = \{1, 2, \ldots, N\}$ and let $i, j, \in V$. For $p, p' \in S_n$, let $\psi(p) = i$ and $\psi(p') = j$. Let $F$ be the multivalued map in (39). The theoretical transition matrix for $F$ under $n$ questions is denoted by $T^{(th)}_{n}(\varphi) = (T^{(th)}_{n,ij})$, where

$$T^{(th)}_{n,ij} = \begin{cases} 1 & \text{if } p' \in F(p) \\ 0 & \text{otherwise.} \end{cases}$$

(40)

$T^{(th)}_{n,ij}$ captures all theoretically admissible transitions between states in $S_n$. Each entry $T^{(th)}_{n,ij} = 1$ indicates that there is a transition from state $i$ to $j$ in one step. Hence, $T^{(th)}_{n,ij}$ gives all possible paths in $S_n$ that any observation can take.

Example 23. From Figure 4, we have $T^{(th)}_{n}$ for $n = 1$ and $n = 2$, as given below

$$T^{(th)}_{1} = \begin{bmatrix} 1 & 1 \\ 1 & 1 \end{bmatrix}, \quad T^{(th)}_{2} = \begin{bmatrix} 1 & 1 & 0 & 0 & 0 & 1 & 0 & 1 \\ 1 & 1 & 0 & 0 & 0 & 1 & 0 & 1 \\ 0 & 0 & 1 & 1 & 1 & 1 & 0 & 1 \\ 0 & 0 & 1 & 1 & 1 & 0 & 1 & 0 \\ 0 & 1 & 0 & 1 & 1 & 0 & 0 & 0 \\ 0 & 1 & 0 & 1 & 1 & 1 & 0 & 0 \\ 1 & 0 & 1 & 0 & 0 & 1 & 1 \\ 1 & 0 & 1 & 0 & 0 & 0 & 1 & 1 \end{bmatrix}. \quad (41)$$

Because the digraph in $S_1$ is the same as the digraphs in $\mathcal{S}_1^{(c,\mathcal{F})}, \varphi_{[\Delta]} \in \mathcal{S}_2$ (Example 19), the matrix encoding transitions in $S_1$ is the same as the matrix encoding transitions in $\mathcal{S}_1^{(c,\mathcal{F})}$. The $2 \times 2$ submatrices of entries all equal to $1$ (in bold numbers) in $T^{(th)}_{2}$ correspond to transitions in $\mathcal{S}_1^{(c,\mathcal{F})}$. The $2 \times 2$ zero submatrices in $T^{(th)}_{2}$ (in bold) denote the nonallowable transitions between states with the same significance (Theorem 18(a)).

3.1. Properties of $T^{(th)}_{n}$. We give some elementary results for $T^{(th)}_{n}$.

Theorem 24. (a) The digraph $\mathcal{S}_{T^{(th)}_{n}}$ is $2^n$-regular; that is, the in- and out-degree of all its vertices is $2^n$.

(b) The largest eigenvalue of $T^{(th)}_{n}$ is $\lambda_{max}(T^{(th)}_{n}) = 2^n$, with associated eigenvector $\nu_1 = 1$.

(c) Consider trace $(T^{(th)}_{n}) = N$.

(d) Consider det$(T^{(th)}_{n}) = 0$.

Proof. (a) This is a consequence of Theorem 15.

(b) This is a consequence of (a) and the Perron-Frobenius theorem [14].

(c) Let $\psi(p) = i$. From the definition of self-transition, $\varphi_{[i]}(p) = p$ for any $p \in S_n$. Hence, $T_{n,ii}^{(th)} = 1$ for $i = 1, 2, \ldots, N$.

(d) Let $p = (x, y)$ and $p' = (x', y)$ be points in $S_n$ such that

$$x = x_0x_1\cdots x_{n-2}x_{n-1},$$
$$y = i_0i_1\cdots i_{n-2}i_{n-1},$$
$$x' = x_0x_1\cdots x_{n-2}x_{n-1}^*, \quad \text{where } x_{n-1}^* \text{ is given in (16).} \quad (42)$$

Claim. $\mathcal{J}_{p} = \mathcal{J}_{p'}$, where $\mathcal{J}_{p}$ and $\mathcal{J}_{p'}$ are given in (27).

The case where $n = 1$ is given in Example 23. We prove our claim for $n = 2$. By definition of self-transition, $\varphi_{[i]}(p) = p$ and $\varphi_{[i]}(p') = p'$. It is clear that $\varphi_{[i]}(p) = p'$ and $\varphi_{[i]}(p') = p$. Let

$$\varphi_{[0]}(p) = p_1,$$
$$\varphi_{[0]}(p') = p_2. \quad (43)$$

Observe that

$$\varphi_{[0]}(p') = \varphi_{[0]}(\varphi_{[1]}(p)) = \varphi_{[1]}(p) = p_2,$$
$$\varphi_{[0]}(p') = \varphi_{[0]}(\varphi_{[1]}(p')) = \varphi_{[1]}(p') \quad (44)$$

Since $p$ and $p'$ have the same image for all $\Delta \in \mathcal{C}_2$, $\mathcal{J}_{p} = \mathcal{J}_{p'}$, as claimed.

Our claim implies that rows of $T^{(th)}_{2}$ associated with $p$ and $p'$ are the same. Because of these repeating rows, det$(T^{(th)}_{2}) = 0$. The proof can be readily extended to the general case and is treated in exactly the same manner.

3.2 Subshift of Finite Type. Let $\omega_j, j \in V = \{1, 2, \ldots, N\}$. If observation $k$ is in state $s_j \in S_n$ after $t$ time steps, we will write $p^k_j \in s_j$ to indicate that more than one observation may be in $s_j$. We associate with the orbit $\mathcal{O}_p(k)$ a sequence of symbols
\[ w = (w_0, w_1, \ldots, w_i, \ldots) \text{, where } w_j = j \text{ if } p_j^k \in s_j. \]

Denote the corresponding symbol space of one-sided sequences of \( T_n^{(th)} \) by
\[
\Sigma_n^{(th)} = \{ w = (w_0, w_1, \ldots) \mid T_n^{(th)} \rightleftharpoons \Sigma_n^{(th)}, \forall i \in \mathbb{N}_0, w_i \in V \}. \tag{45}
\]

The equation of motion in \( S_n \) is given by the shift map \( \Sigma_n^{(th)} \to \Sigma_n^{(th)} \) defined by
\[
\sigma_n^{(th)}(w) = w_i' \text{ where } w_i' = w_{i+1} \tag{46}
\]

Definition 25 (see [15]). The pair \((\sigma_n^{(th)}, \Sigma_n^{(th)})\) is called the subshift of finite type (SFT) determined by \( T_n^{(th)} \).

The SFT determined by \( T_n^{(th)} \) captures the exact detail of all possible itineraries of observations in \( S_n \). Many dynamical properties of an SFT depend on the structure of its associated transition matrix or digraph.

Definition 26 (see [16]). (i) A transition matrix \( T \) is irreducible if for each pair \((i, j)\), there exists \( \ell > 0 \) so that \( T^\ell \neq 0 \). Otherwise, \( T \) is reducible. (ii) The digraph \( G_T = (V, E) \) associated with \( T \) is strongly connected if it is possible to get from any vertex to any other one by traversing a sequence of edges as directed by \( T \). (iii) If there exists \( \ell > 0 \) such that \( T^\ell > 0 \) for all \( \ell > \ell' \), then \( T \) is primitive. (iv) Let \( X \) be any set. A continuous map \( f : X \to X \) is (topologically) transitive if, for all nonempty open sets \( U, U' \subset X \), there exists \( \ell \geq 0 \) such that \( f^\ell(U) \cap U' \neq \emptyset \). (v) If there is \( \ell' > 0 \) such that \( f^\ell(U) \cap U' \neq \emptyset \) for all \( \ell > \ell' \), then \( f \) is (topologically) mixing.

Consider the SFT given by \((\sigma_T, \Sigma_T)\). The following results concern dynamical properties of a transitive SFT and algebraic properties of its transition matrix. (i) The shift map \( \Sigma_T \) is transitive (resp., mixing) if and only if \( T \) is irreducible (resp., primitive). (ii) \( T \) is irreducible if and only if the digraph \( G_T = (V, E) \) is strongly connected. In that case we say that \( V \) is irreducible. (iii) A nonnegative, irreducible matrix with a positive element on the main diagonal is primitive.

**Theorem 27.** \( T_n^{(th)} \) is irreducible.

**Proof.** We prove by induction on \( n \). From Example 23, \( T_{1ij}^{(th)} = 1 \) for all \((i, j)\) so \( T_n^{(th)} \) is irreducible for \( n = 1 \). Assume that \( T_n^{(th)} \) is irreducible for \( n = m \). Then the digraph \( G_m^{(th)} \) is strongly connected, and \( S_m \) is irreducible. We prove that \( G_m^{(th)} \) is strongly connected to \( n = m + 1 \).

Recall that transitions in \( S_{m+1} \) are under the set \( C_{m+1} \).

From (37), this set can be expressed as \( C_{m+1} = \mathcal{D}_{m+1} \cup (C_{m+1} \setminus D_{m+1}^{(1)}) \), where \( D_{m+1}^{(1)} \) is the set associated with transitions in the irreducible set \( \mathcal{D}_m^{(cij)} = S_m \), \( c \in \{0, 1\} \) and \( i_j \in I_{m+1} \). With the additional transitions under \( C_{m+1} \setminus D_{m+1} \), we show that

(i) the set \( \mathcal{D}_m \subset S_{m+1} \) (given in (33)) is irreducible;

(ii) there is a path to and from any pair \( p, p' \), where \( p \in \mathcal{D}_m^{(0)} \) and \( p' \in \mathcal{D}_m^{(1)} \).

We prove (i) by showing that there is \( p \in \mathcal{D}_m^{(cij)} \) such that, for all \( i_j \neq i \), there is a transition from \( p \) to \( p' \in \mathcal{D}_m^{(cij)} \). By Theorem 16, \( \varphi_{[\sigma(p), m]}^{(m+1)}(p) = p \) for any \( p \in \delta_{m+1} \). Let
\[
p_0 = (cc \cdots cc^*, i_0 i_1 \cdots i_{m-1} i_m) \tag{47}
\]

Observe that all \( p_j \)’s have the same fitness states but distinct significance states. In particular, each \( p_j \) is contained in a distinct subset \( \mathcal{D}_m^{(cij)} \). This vertical transition allows all \( p_j \in \mathcal{D}_m^{(cij)} \) to visit a distinct \( \mathcal{D}_m^{(cij)} \) at most \( m \) steps. Hence, \( \mathcal{D}_m^{(c)} \) is irreducible. To show (ii), take
\[
p = (00 \cdots 0, m(m - 1) \cdots 10) \in \mathcal{D}_m^{(0)} \tag{48}
\]

Under \( \Delta = I_{m+1} \), there is a reversible transition \( p \xrightarrow{[\Delta]} p' \).

From (i), (ii), and the irreducibility of \( T_n^{(th)} \), there is a path between any pair \( p, p' \in \delta_{m+1} \). Hence, \( G_m^{(th)} \) is strongly connected and \( T_n^{(th)} \) is irreducible, as desired.

**Corollary 28.** \( T_n^{(th)} \) is primitive.

**Definition 29** (see [15]). The topological entropy of the shift map \( \Sigma_T : \Sigma_T^+ \to \Sigma_T^+ \) is defined by
\[
h_{\text{top}}(\sigma_T) = \lim_{m \to \infty} \frac{\ln(|\mathcal{W}(m)|)}{m}, \tag{49}
\]
where \( \mathcal{W}(m) \) is the set of allowable sequences of length \( m \geq 1 \).

A continuous map \( f \) on a compact metric space \( X \) is chaotic if \( h_{\text{top}}(f) > 0 \) [17]. The topological entropy for SFTs is given by the following theorem [15].

**Theorem 30.** Let \( T \) be a transition matrix and let \( \Sigma_T : \Sigma_T^+ \to \Sigma_T^+ \) be the associated SFT. Then
\[
h_{\text{top}}(\sigma_T) = \ln(\lambda_{\max}), \tag{50}
\]
where \( \lambda_{\max} \) is the maximum eigenvalue of \( T \).
Since \((\sigma_{n,0}(\text{th}), \Sigma_{n,0}(\text{th}))\) is the associated subshift of the multi-valued map \(F\) in (39), one has

\[
h_{\text{top}}(F) = h_{\text{top}}(\sigma_{n,0}(\text{th})) = \ln(2^\mathcal{H}) = n \ln 2 > 0.
\]

4. Dynamics from Data

Given multivariable longitudinal binary data of dimension \(n\), every observed orbit is an orbit of an SFT determined by \(T_{n,0}(\text{th})\). Dynamics of real-world longitudinal data however is not often defined by an SFT. Data usually selects certain paths given by \(T_{n,0}(\text{th})\) and may sometimes stay in a particular subspace of \(S_n\).

4.1. Nonstationary SFT. Let \(p, p’ \in S_n, \psi(p) = i, \text{ and } \psi(p’) = j\). For each \(t \geq 0\), denote by \(T_{n,2}(\text{data})\) the matrix that records observed transitions that occur in the longitudinal data from time \(t\) to \(t + 1\), where

\[
(T_{n,2}(\text{data}))_{ij} = \begin{cases} 
1 & \text{if } \exists k \in K, \text{ such that } p \xrightarrow{k} p’ \\
0 & \text{otherwise.}
\end{cases}
\]

We note that \(T_{n,2}(\text{data})\) is defined over an interval of time and that \(T_{n,2}(\text{data})\) may vary with time. Some allowable transitions between states given by \(T_{n,2}(\text{th})\) might not occur in the observed data so \(T_{n,2}(\text{data}) \neq T_{n,2}(\text{th})\). For the case where \(T_{n,2}(\text{data})\) is constant we write \(T_{n,2}(\text{data}) \equiv T_{n,2}(\text{data})\) and we can define the SFT given by the pair \((\sigma_{n,2}(\text{data}), \Sigma_{T_{n,2}(\text{data})})\).

If \(T_{n,2}(\text{data})\) is not constant, then we have a sequence of matrices

\[
A = \{T_{n,2}(\text{data})\}_{t \geq 0}.
\]

Given \(A\), define

\[
\Sigma_A^{(\text{data})} = \{w = (w_1, w_2, \ldots, w_T) \in \Sigma_{T_{n,2}(\text{th})}^+, \text{ such that } (T_{n,2}(\text{data}))_{w_i w_{i+1}} = 1\}.
\]

We call \(\Sigma_A^{(\text{data})}\) the nonstationary symbolic space restricted by the sequence of matrices \(A\). The shift takes place as usual in \(\Sigma_A^{(\text{data})}\) and is denoted by \(\sigma_A : \Sigma_A^{(\text{data})} \rightarrow \Sigma_A^{(\text{data})}\). We refer the reader to [19–21] for a discussion on nonstationary SFT.

Definition 31. The pair \((\sigma_A, \Sigma_A^{(\text{data})})\) is the nonstationary SFT (NSFT) determined by the sequence of matrices \(A\).

Visualization of dynamics of longitudinal data defined by an NSFT is illustrated by a sequence of directed graphs called a Bratteli diagram [9, 10]. Equivalently we may plot orbits of observations in \(S_n\) over time. Figure 6(a) illustrates the orbits of a population in a subset of \(S_3\) over time.

4.2. Population Dynamics. We discuss the longitudinal data of a population of \(K > 1\) observations. Aside from all possible paths that an observation can take in \(S_n\), we are also interested in the number of observations on paths. Because it is possible for more than one observation to occupy a state in \(S_n\) at a given time, we can consider the number of observations that follow the same transition in \(S_n\).

In general, given a transition matrix \(T\) (e.g., those in (40) or (52)), standard analysis is to accumulate number of transitions between states, and from this construct the associated stochastic transition matrix. Construction of associated
transition and stochastic matrices on states of $S_n$ can then follow as usual. In what follows, let $V$ denote a finite index set with $|V| \geq 2$ and $i, j \in V$.

**Definition 32.** Let $H_t(i)$ be the number of observations in state $i$ at time $t$. The density matrix at time $t$ is defined by

$$D_t = (d_{t,ij}),$$

where $d_{t,ij}$ is the number of observations in state $i$ at time $t$ that go to state $j$ at time $t + 1$. The (net) flux of state $i$ at time $t$ is defined by

$$F_t(i) = H_{t+1}(i) - H_t(i).$$

Let $\epsilon_{t,ij} = d_{t,ij} - d_{i,j}$, $i, j \in V$. The flux in (56) can also be expressed as

$$F_t(i) = \sum_j \epsilon_{t,ij}.$$  \hspace{1cm} (57)

From (56) and (57), we have

$$H_t(i) = \sum_j d_{t,ij}, \quad H_{t+1}(i) = \sum_j d_{t+1,ij}. \hspace{1cm} (58)$$

Let $H_t$ be a row vector whose $i$th entry is $H_t(i)$. We will refer to $H_t$ as the observed capacity vector at time $t$. Given the initial observed capacity vector $H_0$, there are two methods that we can use to determine $H_{t+1}$.

(i) **Nonhomogenous Case.** From data, we are encouraged to construct a probability matrix based directly on the density matrices $D_t$. For each $D_t$, we construct a time-dependent probability matrix $P_t = (P_{t,ij})$, where

$$P_{t,ij} = \begin{cases} 
\frac{d_{t,ij}}{\sum_j d_{t,ij}}, & \text{if } \sum_j d_{t,ij} \neq 0 \\
0 & \text{otherwise.}
\end{cases} \hspace{1cm} (59)$$

The capacity vector $H_{t+1}$ is given by the product

$$H_{t+1} = H_t \cdot P_t$$

$$= H_0 \cdot \prod_{m=0}^t P_m. \hspace{1cm} (60)$$

We show that the capacity $H_{t+1}(i)$ in (56) agrees with the $i$th entry of (60). It is trivial if $\sum_j d_{t,ij} = 0$ for all $t$. Otherwise we have

$$H_{t+1}(i) = H_t(i) + F_t(i)$$

$$= H_t(i) + \sum_j (d_{t,ij} - d_{t,ij})$$

$$= H_t(i) + \sum_j \left( P_{t,ij} \sum_i d_{i,j} - P_{t,ij} \sum_j d_{t,ij} \right).$$

(ii) **Homogenous Case.** Let $D_t$ be the density matrix at time $t$ and let

$$D^{(data)} = \sum_{t=0}^{T-1} D_t \hspace{1cm} (62)$$

be the accumulated density matrix of the data over the observation period. Define the mean density matrix by

$$D = \frac{1}{T} D^{(data)}. \hspace{1cm} (63)$$

Suppose $D$ is irreducible. Define the mean probability matrix from $D$ by $P_D = (P_{D,ij})$, where

$$P_{D,ij} = \frac{D_{ij}}{\sum_j D_{ij}}. \hspace{1cm} (64)$$

The capacity vector at $t + 1$ is given by the product

$$H_{t+1} = H_t \cdot (P_D)$$

$$= H_0 \cdot (P_D)^t. \hspace{1cm} (65)$$

The probabilities in (64) are based on observed frequencies at which one state follows another. The transition probabilities of a Markov model using states in $S_n$ are then estimated. Markov modeling on the bigger space $S_n$ may give better results in generating data as $S_n$ is a more detailed space than a space where order of variable is fixed (e.g., $M'_n$).

**Definition 33.** A set of observations $K'$ cluster in $S_n$ if for all $k \in K'$, there exists $R \subset S_n$ and time interval $I$ such that the orbit $O(k) \subset R$ for all $t \in I$.

An advantage in using the bigger space $S_n$ to analyse multivariable longitudinal data is that all possible clusterings in stable variables are revealed. We can also visualize in $S_n$ the shift in clusters from one region $R$ to another region $R'$. There is much interesting information that we can gather from a cluster in a subset $R$ of $S_n$. Clustering in $S_m$ ($m \neq n$) defined in (32) involves observations with the same stable $n - m$ variables. Subsets $L_m$ are important as they automatically determine which variables are trivial in the analysis. We either reduce analysis from $S_n$ to $L_m$ or replace the $n - m$ constant variables with other nonconstant variables that are of interest to purpose. In addition, orbits that spend most (if not all) of the time in $L_m$ have strong correlation among the $n - m$ variables.
Table 5: Agincourt questionnaire with corresponding coded answer and frequency of answer change in the population.

| Question | Answer | Code | \( f_i^p \) |
|----------|--------|------|-------------|
| \( Q_1 \): Is the biological mother present (>6 months)? (BM) | Yes | 1 | 760 |
| \( Q_2 \): Is the household headed by a minor? (HH) | Yes | 0 | 4 |
| \( Q_3 \): Is there an adult death in the household? (AD) | Yes | 0 | 119 |

Table 6: Total transitions from state \( i \rightarrow j \) (\( i, j = 23, 24 \)) in defaulting and nondefaulting household, together with the odds ratios (95% confidence interval and \( P \) value).

| State \( i \rightarrow j \) | Defaulting | Nondefaulting | Odds ratio (95% CI; \( P \) value) |
|--------------------------|-------------|---------------|----------------------------------|
| 23 \( \rightarrow \) 23 | 256 | 63 | 1.59 (1.17 to 2.17; \( P = 0.0031 \)) |
| 23 \( \rightarrow \) 24 | 238 | 84 | 1.00 (0.75 to 1.33; \( P = 0.9925 \)) |
| 24 \( \rightarrow \) 23 | 260 | 96 | 0.94 (0.72 to 1.24; \( P = 0.6653 \)) |
| 24 \( \rightarrow \) 24 | 214 | 99 | 0.70 (0.53 to 0.92; \( P = 0.0110 \)) |

5. Application

We illustrate our method using the \( n = 3 \) demographic binary questions taken from Agincourt [22]. With purpose \( \mathcal{P} \) to investigate the effect of household change on a child’s educational progress, the three questions in (4) are associated with household change and are all of interest to \( \mathcal{P} \). Table 5 gives the question (indexed by 0, 1, and 2, resp.) with associated variables (BM, HH, and AD), favourable/unfavourable coding, and frequency of change.

The longitudinal data consists of \( K = 188 \) observations with no missing data. Each household is surveyed each year, for nine years [22], and the population is constant throughout the observation period; that is, no households enter nor leave the population. Using (20), the frequency relation in the population \( P \) is \( f_i^P \leq f_j^2 \leq f_j^P \). The number of unfavourable = 0 answers (over 1692 answers) is \( Q_5: 844 (49.9\%) \), \( Q_1: 2 (0.1\%) \), and \( Q_2: 71 (4.2\%) \). We expect that this, together with the very small value of \( f_1^P \), will give clustering in the question order 1***, where \( Q_1 = 1 \).

Figure 6(a) illustrates orbits of households in \( S_3 \) over time, where a red edge denotes a transition to the left, a green edge is a transition to the right, and a blue edge is a self-transition. Most of the orbits are in

\[
\mathcal{D} = [21, 22, 23, 24, 29, 30, 31, 32] = \{(x, y) : x = 1 ** *, y = 1 ** * \} \tag{66}
\]

and are characterised by the favourable property of being headed by an adult (i.e., \( Q_1 = 1 \)). Of the 179 households that stay in \( \mathcal{D} \), 159 distinct orbits are found. However, we see from Figure 6(b) that the number of state visits in \( S_3 \) is dominant in states 23 = (110, 120) and 24 = (111, 120) so dynamics principally takes place in these two states.

State 23 is characterised by the most stable variable \( HH = 1 \), followed by \( AD = 1 \) and then by \( BM = 0 \). Similarly, state 24 is characterised by the most stable variable \( HH = 1 \), followed by \( AD = 1 \) and then by \( BM = 1 \). Orbits that stay strictly in states 23 and 24 are associated with households headed by an adult and with no adult death during the survey period. Those idle in 23 (resp., 24) have mothers away (resp., present) during the survey period. Households that transition from 23 to 24 are characterized by mother out- to in-migration, while transitions from 24 to 23 denote in- to out-migration.

With regard to purpose, we define educational default by the number of years that a child has failed in his school life. A household with a child who has failed 4 years or more in his school life is classified as defaulting. Orbits in Figure 6(a) are then split into defaulting and nondefaulting populations, as shown in Figures 7(a) and 7(b), respectively.

Note that if we include a fourth question

\( Q_3: \) is the household defaulting (=0) or nondefaulting (=1)?

then orbits will be plotted in \( S_4 \), as seen in Figure 5. Orbits that cluster on the left are the defaulting households \( (Q_4 = 0) \), while those on the right are nondefaulting \( (Q_4 = 1) \).

Figure 8 gives \( H_i(i) \), the number of observed defaulting and nondefaulting households at each state \( i = 23, 24 \) from \( t = 1999 \) to \( t = 2007 \). It is clear that, for both subpopulations, there is an exchange of numbers between states 23 (BM-out) and 24 (BM-in). Figures 9(a) and 9(b) illustrate the orbits of defaulting and nondefaulting households over time, and the accumulated number of visits in \( S_4 \), respectively.

Table 6 gives the (accumulated) number of state transitions \( i \rightarrow j \), \( i, j \in \{23, 24\} \) for both subpopulations. Using odds ratio, we have the value 1.59 (>1) for transition 23 \( \rightarrow \) 23, which means that once mothers from defaulting households out-migrate, they take long to return to their households. Out-migrating mothers are then more likely to be away from home in the defaulting households.
6. Concluding Remarks

By defining a specific swap operation on multivariable longitudinal data, we have imposed dynamics on data. No approximations are made and orbit of an observation in the 2-dimensional space $S_n$ can be decoded back to the observation’s original data. By including the order of variables in our analysis, we have introduced new states, along with an objective criterion of relative fitness and identification of subshift. We have only considered binary-valued variables but the method may be generalized to $m$-ary valued multivariable longitudinal data. Although the method of orbits is nonstatistical, it can however be used to aid in statistical analysis.

The advantage in plotting orbits in $S_n$ is that information of change can be extracted directly from the visualized orbits. In addition, orbits in $S_n$ facilitate the identification of cause and effect, of preceding events that might uniquely and usefully associate with change. Frequency of change is a property taken directly from the data so that, under our reordering operation, any practitioner with the same favourable and unfavourable coding will find the same ordering of questions and arrive at the same analysis of longitudinal data.

For $24 \rightarrow 24$ we have odds ratio of $0.70 (< 1)$ indicating that in-migrating mothers are more likely to stay at home in the nondefaulting households. Both odds ratios have significant $P$ values and these support our hypothesis that mother out-migration places child educational progression at risk. We have no strong evidence that mother out-migration ($24 \rightarrow 23$) is more likely in the defaulting households nor that in-migration ($23 \rightarrow 24$) is more likely in nondefaulting households.

Figure 7: Orbits in $S_3$ of (a) defaulting and (b) nondefaulting households.

Figure 8: Number of defaulting and nondefaulting households in states 23 and 24 for $t = 1999$ to $t = 2007$. 
Figure 9: (a) Orbits of defaulting (left cluster) and nondefaulting (right cluster) households in $S_4$, over time. (b) Accumulated number of visits to each state of $S_4$.

Conflict of Interests

The authors declare that there is no conflict of interests regarding the publication of this paper.
