Influence of the asymmetric excited state decay on coherent population trapping

H. S. Borges, M. H. Oliveira & C. J. Villas-Boas

Electromagnetically induced transparency (EIT) is an optical phenomenon which allows a drastic modification of the optical properties of an atomic system by applying a control field. It has been largely studied in the last decades and nowadays we can find a huge number of experimental and theoretical related studies. Recently a similar phenomenon was also shown in quantum dot molecules (QDM), where the control field is replaced by the tunneling rate between quantum dots. Our results show that in the EIT regime, the optical properties of QDM and the atomic system are identical. However, here we show that in the strong probe field regime, i.e., “coherent population trapping” (CPT) regime, it appears a strong discrepancy on the optical properties of both systems. We show that the origin of such difference relies on the different decay rates of the excited state of the two systems, implying in a strong difference on their higher order nonlinear susceptibilities. Finally, we investigate the optical response of atom/QDM strongly coupled to a cavity mode. In particular, the QDM-cavity system has the advantage of allowing a better narrowing of the width of the dark state resonance in the CPT regime when compared with atom-cavity system.

It is well known that quantum interference between different excitation paths can modify the optical response of a system, giving rise for example to the suppression of absorption of the incident light when the interference between these channels is destructive. Optical nonlinear effects, such as electromagnetically induced transparency (EIT)\(^1,2\), result in the suppression of a weak probe field absorption in a narrow spectral window accompanied by an enhancement of its nonlinear susceptibility and an abrupt change of the refraction index\(^3,4\). The electromagnetically induced transparency phenomenon is associated with another process named coherent population trapping (CPT)\(^5,6\), which is characterized by a dark state written as a coherent superposition of the ground states of the system. In this context, quantum interference and coherent effects have been widely investigated and demonstrated in various three-level systems in \(\Lambda\)-configuration, which can be modelled in atomic\(^7\) and semiconductor systems, for example coupled quantum dots (QDM - Quantum Dot Molecule)\(^8\). Nowadays we can find a huge number of theoretical and experimental studies on EIT, presenting applications such as slowing down of light pulses\(^9\), quantum memories in atomic ensembles\(^10,11\) or in optical cavities\(^12\), cooling down trapped atoms\(^13-15\), to enhance multi-wave mixing processes\(^2,16,17\) among many others.

Placing the atom or the QDM inside an optical cavity, their couplings with the probe field is replaced by coupling with a cavity mode (strength \(g\)), which is driven by the probe laser. For practical proposes the interaction of single emitters (atom or quantum dot) with optical cavity modes has a fundamental role, enabling a significant enhancement of the light-matter coupling and the increase of the efficiency of photon collection. In the atom–cavity system the EIT effect can be observed through the transmission spectrum of an incident laser field (probe laser), which will be entirely transmitted at resonance if the control field is present\(^11\). In this context it is important remind that the linewidth of the transmitted field depends on the ratio between the squares of the control field Rabi frequency \(\Omega_c\) and atom–cavity coupling \(g\), which is valid when there is no decay or dephasing on the atomic ground states and when the system is in the EIT regime.

In this work we investigate the difference between the optical response of two distinct three-level systems in \(\Lambda\)-configuration, i.e., a single atom and QDM. In both systems there are two ground states coupled to the same excited state – see Fig. 1(a,b). In the free-space the couplings are mediated by the probe laser and by the control field for atomic system. For the QDM, the control laser beam is replaced by the electron tunneling between the quantum dots (with tunneling rate \(T_e\)), which can be controlled by an external electric field\(^19\). This effect is known
as tunneling induced transparency (TIT) due to the critical role of tunneling in the appearance of transparency in QDMs\(^{20,21}\) and allows for applications similar to those we find in atomic systems, e.g., slow down of light pulses\(^{20}\) or cavity linewidth narrowing\(^{22,23}\).

Our results show a notable difference in the optical response of these systems when the Rabi frequency of the probe laser is comparable or larger than the Rabi frequency of the control field (tunneling rate), i.e., \(\Omega \gtrsim \Omega_{T}\). Besides, we note a very appreciable difference in the transmission spectrum of the cavity when we have atom or QDM coupled to it and when we are in the limit \(\Omega_{C} \to 0\) or \(T_{e} \to 0\), respectively. In those limits and when all the fields are on resonance, while the transmission of the atom–cavity system reaches an empty cavity situation, the QDM–cavity presents an extremely narrow transmission peak. Thus, here we show that QDM works out more efficiently to induce cavity-linewidth narrowing\(^{22–25}\) than atoms. Our analysis shows that these features occurs due to nonlinear effects, which become more pronounced in the weak control field limit (CPT regime). We show that the crucial parameter which allows for the enhancement of the nonlinear effects in EIT/CPT processes is the asymmetric decay rate of the excited state.

Results

EIT and TIT in Free Space. Both the atom and the QDM can be modelled by the same general Hamiltonian, i.e., a three-level system in a \(\Lambda\)-configuration with two ground states, \(|1\rangle\) and \(|2\rangle\), and an excited one \(|3\rangle\), as shown in Fig. 1. The levels \(|1\rangle\) and \(|3\rangle\) (transition frequency \(\omega_{31}\)) are coupled by a probe field with Rabi frequency \(\Omega_{P}\) while the levels \(|2\rangle\) and \(|3\rangle\) (transition frequency \(\omega_{32}\)) are either coupled by a classical control field (frequency \(\omega_{C}\)) with Rabi frequency \(\Omega_{C}\) or by a tunnelling process with tunnelling rate \(T_{e}\) for the atomic or QDM system, respectively. In the QDM system, the energy levels correspond to the excitonic states (electron-hole pair held together by their attractive Coulomb interaction), where the ground state \(|1\rangle\) is the QDM without any excitation, and the states \(|2\rangle\) and \(|3\rangle\) are the exciton states with indirect and direct character, respectively\(^{26}\). Considering the rotating wave approximation, the Hamiltonian that describes both atomic and QDM systems (without temporal dependency), can be written in the interaction picture as (\(h = 1\))

\[
H_{I} = -\Delta_{p} \sigma_{11} - \frac{\Omega_{P}^{2}}{2} \sigma_{31} + \Theta \sigma_{32} + h. \text{ c. e.}
\]

(1)

being \(\Delta_{p} = \omega_{31} - \omega_{p}\) the detuning between the \(|1\rangle \leftrightarrow |3\rangle\) transition and the probe field \((\omega_{p})\) frequencies. Here was considered that the control field frequency \((\omega_{C})\) is resonant with the transition \(|2\rangle \leftrightarrow |3\rangle\), i.e., \(\Delta_{C} = 0\). For the QDM system we assume a specific value of the external field applied along the growth direction of nanostructure.
such that the direct and indirect exciton states are resonant, i.e., $\omega_{12} = 0$. The atomic or QDM operators are represented by $\sigma_{kl} = |k\rangle\langle l|$ for the atom or for the QDM, respectively, and $\text{h.c.}$ stands for Hermitian conjugate. The dissipation of the system can be included in the dynamics of system through the master equation

$$\frac{d\rho}{dt} = -i[H_\text{int}, \rho] + \sum_{k=i}^{N} \sum_{l=1,2}\frac{\Gamma_{il}}{2}(2\sigma_{lk}\rho\sigma_{ki} - \sigma_{kl}\rho\sigma_{li} - \rho\sigma_{ki}\sigma_{lk})$$

being $\Gamma_{il}(k \neq i)$ the decay rate of the level $|k\rangle$ to level $|l\rangle$ and $\Gamma_0$ the dephasing rate of the level $|1\rangle$. Here we can point out the main difference between the atomic and QDM systems: while usually we find $\Gamma_0 \approx \Gamma_1 \approx 0$ for atoms, $\Gamma_1 \approx 0$ and $\Gamma_0 \approx 0$ for QDM. This difference will introduce a strong modification on the nonlinear behaviour of atoms and QDM as we discuss below. Of course, one could find an atomic system in $\Lambda$-configuration where $\Gamma_1 \gg \Gamma_2$ and then its optical response would be similar to that of the QDM we are analysing here.

In the context of QDM system, it is well known that there may be incoherent tunnelling process between the dots assisted by acoustic phonons or photons. However as we are assuming in our model that the coupling between system and reservoir is weak, this kind of incoherent process can be neglected since it requires the absorption and the re-emission of a phonon (or even a photon), i.e., second order process. In fact was demonstrated experimentally in the27 that the rate associated to this incoherent process (also called inelastic tunnelling) is zero when the resonance condition is fulfilled. Moreover, it was recently shown in30 an analytical expression for this rate, which is in turn directly proportional to the difference of energy between the levels involved in the process. As in our model we assume that the levels $|2\rangle$ and $|3\rangle$ are resonant ($\omega_3 = \omega_2$) for the QDM system, the rate associated to incoherent tunnelling between the dots is zero, i.e., we can assume $\Gamma_1 = 0$.

We can easily obtain the steady state solution for the master equation (2). Considering different regimes of control (tunnelling process) and probe fields we immediately see expressive differences of the optical response for atomic and QDM systems, here quantified by Absorption and Dispersion defined, apart from a scaling factor, as $\text{Im}(\sigma_{13})$ and $\text{Real}(\sigma_{13})$, respectively. In all plots of Fig. 2 we have considered $\Gamma_1 = \Gamma_2 = 0.5\Gamma$ for the atoms and $\Gamma_1 \approx \Gamma$ and $\Gamma_2 = 0$ for the QDM, so that in both cases the total decay rate of the excited state $|3\rangle$ is $\Gamma$. Throughout this work we have neglected the other decoherence and dissipation rates, i.e., $\Gamma_3 = \Gamma_4 = 0$, since they are much smaller than the decay rates of the excited state and also because they destroy dark state of the system, thus making difficult the comparison between the optical responses of the atomic and QDM systems29-30. We note that, when $\Omega_p \ll \Theta = (\Omega_c, T_c)$, i.e., in the regime of parameters known as EIT regime (or even in the Autler-Townes regime), the optical response of the system is independent on the decay rate of the excited state $|3\rangle$ to the ground state $|2\rangle$, as we can see in Fig. 2(a). However, for $\Omega_p \gg \Theta$, i.e., in the regime known as CPT (coherent population trapping) we can see a strong difference between the atomic and QDM optical responses, as shown in Fig. 2(c).
absorption in the region around the transparency window. The origin of such difference is on the decay rate $\Gamma_{32}$, which is non-null for the atomic system but null for QDM. In Fig. 2(b,d) we plot the populations of the states $|1\rangle$, $|2\rangle$, and $|3\rangle$ for atomic and QDM systems (the population of the excited state $|3\rangle$ is close to zero in all cases), for EIT and CPT regimes, respectively. Again, there is an expressive difference between the behaviours of the populations of the atom and of the QDM in the CPT regime. In particular, for QDM the populations $P_{1}$ and $P_{2}$ are modified only for resonant probe field, i.e., for $\Theta = 0$. The origin of such difference between QDM and atoms is an effective decay from level $|1\rangle$ to $|2\rangle$, described by the effective Lindbladian $\Gamma_{2}^{\text{eff}} = 2(\sigma_{1\mu}\rho_{12} - \sigma_{1\mu}\rho_{12})$, which arises only for non-null $\Gamma_{32}$, being $\Gamma_{2}^{\text{eff}} = P_{1}\Gamma_{32}$. In the limit of $\Theta \to 0$ and for $\Gamma_{32} = 0$ we would have a two-level system driven by a probe field (Rabi frequency $\Omega_{p}$) and with a total decay rate of the excited state given by $\Gamma$. In this case, the steady population of the excited state is $P_{3} = 1/2(1 + \{\sigma_{33} - \sigma_{11}\}) = P_{3}/(4\Gamma_{2}^{\text{eff}} - 2\Gamma_{32})$. Introducing the effective decay rate from level $|1\rangle$ to $|2\rangle$ in the dynamics of the QDM we can reproduce almost perfectly the populations of the atomic system, as we see in the inset of Fig. 2(d) (only exactly on the dark state resonance we see a discordance, which becomes negligible when we decrease even more the value of $\Theta$).

To understand how the decay rate $\Gamma_{32}$ affects the optical response of our system, it is instructive to analyse the optical susceptibility of the system and its linear and nonlinear components. The polarization density of the system is given by $\chi^{(1)} = \frac{2\Delta_{p}}{2\Delta_{p} - i\Theta - \Theta^{2}}$, $\chi^{(3)} = \frac{4\Delta_{p}^{2} \left[ \Gamma_{12}^{\text{eff}} \right]^{2}}{\Delta_{p}^{2} - 2i\Delta_{p}\Gamma_{2}^{\text{eff}} + 4(\Theta^{2} + 2i\Delta_{p}\Gamma - 4\Delta_{p}^{2})^{2}}$, $\chi^{(5)} = \frac{2\Delta_{p} \left[ -4i\Delta_{p}^{4} - \frac{8\Delta_{p}^{4}}{\Theta^{2}} + \frac{4\Delta_{p}^{4}}{\Theta^{2}} \right] (i\Gamma_{12} - 10\Delta_{p\Gamma} + 2i\Gamma_{31}\Delta_{p}) + 4\Delta_{p}^{2} A + 2\Delta_{p} B \Theta^{2} - 3\Gamma_{12}^{\text{eff}}\Gamma_{2}^{\text{eff}}}{\Delta_{p}^{2} - 2i\Delta_{p}\Gamma_{2}^{\text{eff}} + 4(\Theta^{2} + 2i\Delta_{p}\Gamma - 4\Delta_{p}^{2})^{2}}$,

\begin{equation}
\chi^{(1)} = \frac{2\Delta_{p}}{2\Delta_{p} - i\Theta - \Theta^{2}},
\end{equation}

\begin{equation}
\chi^{(3)} = \frac{4\Delta_{p}^{2} \left[ \Gamma_{12}^{\text{eff}} \right]^{2}}{\Delta_{p}^{2} - 2i\Delta_{p}\Gamma_{2}^{\text{eff}} + 4(\Theta^{2} + 2i\Delta_{p}\Gamma - 4\Delta_{p}^{2})^{2}},
\end{equation}

\begin{equation}
\chi^{(5)} = \frac{2\Delta_{p} \left[ -4i\Delta_{p}^{4} - \frac{8\Delta_{p}^{4}}{\Theta^{2}} + \frac{4\Delta_{p}^{4}}{\Theta^{2}} \right] (i\Gamma_{12} - 10\Delta_{p\Gamma} + 2i\Gamma_{31}\Delta_{p}) + 4\Delta_{p}^{2} A + 2\Delta_{p} B \Theta^{2} - 3\Gamma_{12}^{\text{eff}}\Gamma_{2}^{\text{eff}}}{\Delta_{p}^{2} - 2i\Delta_{p}\Gamma_{2}^{\text{eff}} + 4(\Theta^{2} + 2i\Delta_{p}\Gamma - 4\Delta_{p}^{2})^{2}},
\end{equation}

being $A = \Gamma_{2}^{\text{eff}} - \Gamma_{31}
\Gamma_{32} - \Gamma_{2}^{\text{eff}} + 4\Delta_{p}^{2} (-6I^{2} + 3\Gamma_{31} + \Gamma_{31}\Gamma_{32}) + 4i\Gamma_{2}^{\text{eff}}\Delta_{p}B = -2\Delta_{p} (3\Gamma_{12} - 3\Gamma_{2}^{\text{eff}}) + \Gamma_{31}(\Gamma_{2}^{\text{eff}} - \Gamma_{31}\Gamma_{32}) + i\Gamma_{12}(\Gamma_{2}^{\text{eff}} + \Gamma_{31})$ and $\Gamma_{2}^{\text{eff}} = \Gamma_{2} + \Gamma_{32} = \Gamma_{31} + \Gamma_{32} = \Gamma_{0}$.

The expressions above are valid for any values of $\Theta$ and $\Delta_{p}$ so that these results are valid in both EIT and CPT regimes. From Eq. (3) we see that $\chi^{(1)}$ depends only on the total decay rate of the excited state $\Delta_{p}$ (and is zero if $\Delta_{p} = 0$); this behaviour is shown in Fig. 3(a,d,g,j) as well, where we plot the imaginary part of the optical susceptibility of the medium. On the other hand, the higher order optical susceptibilities ($\chi^{(3)}$ and $\chi^{(5)}$) also help us to mathematically see how $\Gamma_{32}$ affects the optical response of the system in the limit of weak control field:

\begin{equation}
\text{Im} \chi^{(3)} = -\frac{2\Delta_{p}^{2} \left[ -4i\Delta_{p}^{4} - \frac{8\Delta_{p}^{4}}{\Theta^{2}} + \frac{4\Delta_{p}^{4}}{\Theta^{2}} \right] (i\Gamma_{12} - 10\Delta_{p\Gamma} + 2i\Gamma_{31}\Delta_{p}) + 4\Delta_{p}^{2} A + 2\Delta_{p} B \Theta^{2} - 3\Gamma_{12}^{\text{eff}}\Gamma_{2}^{\text{eff}}}{\Delta_{p}^{2} - 2i\Delta_{p}\Gamma_{2}^{\text{eff}} + 4(\Theta^{2} + 2i\Delta_{p}\Gamma - 4\Delta_{p}^{2})^{2}}.
\end{equation}

As can be seen in the expression (6), the first term is independent of $\Theta$ and the second one has $\Theta^{4}$ as denominator and is zero if $\Gamma_{32} = 0$. Such fact indicates that this term is one of the main responsible for the enhancement of the non linear effects of the optical susceptibility associated to $\Gamma_{32}$. In fact, the last term in this expression goes to zero in the limit of $\Theta \to 0$, while the second one becomes more and more relevant in this limit. This is exactly what we observe in Fig. 3: out of the transparency window, decreasing $\Theta$ from $0.5\Gamma_{12}$(EIT regime) to $0.1\Gamma_{12}$ (CPT regime), the maximum (in absolute values) value of $\chi^{(3)}$ has an increasing of the order of 10 times, when $\Gamma_{32} = 0$, but its variation is negligible when $\Gamma_{32} = 0$.

**Cavity EIT and TIT.** Making use of strong QDM/atom-cavity couplings, the effects predicted above could be experimentally investigated at a level of single atom/QDM and used, e.g., in applications such as cavity-linewidth narrowing$^{22-24}$. A single atom or a single QDM coupled to a cavity mode can be described by the following master equation$^{58}$.
\[ \frac{d\rho}{dt} = -i[H_{\text{sys}}, \rho] + \frac{\kappa}{2}(2a a^\dagger - a^\dagger a - \rho a a^\dagger a) + \sum_{i=1}^{3} \sum_{k=2}^{3} \frac{\Gamma_{ik}}{2} (2\sigma_i^a \rho \sigma_k - \sigma_k^a \sigma_i \rho - \rho \sigma_k^a \sigma_i^a), \]

being \( \kappa \) the total decay rate of the intensity of the cavity field and \( a \) and \( a^\dagger \) the annihilation and creation operators associated to the internal cavity mode, respectively. Considering for simplicity the \( |1\rangle \leftrightarrow |3\rangle \) transition resonant to the cavity mode (control field/tunneling), the Hamiltonian \( H_{\text{cav}} \) given in the interaction picture and without time-dependency is \( \hbar = 1 \):

\[ H_{\text{cav}} = -\Delta^c(\sigma_{11} - a^\dagger a) + \left\{ \frac{\epsilon}{2} a + g a \sigma_{11} + \frac{\Theta}{2} \sigma_{22} + h. \text{ c.} \right\}, \]

where \( \Delta^c = \omega - \omega_p \) represents the detuning between the cavity mode (\( \omega \)) and the probe field (\( \omega_p \)) frequencies. Here, we assume that the cavity mode and control field (\( \omega_p \)) frequencies are resonant with the atomic transitions \( |1\rangle \leftrightarrow |3\rangle \) and \( \{2\} \leftrightarrow |3\rangle \), respectively. For the QDM, we assume that the levels \( |2\rangle \) and \( |3\rangle \) are resonant. The atom/ QDM-cavity system is probed by a weak laser represented by a driving field of strength \( \epsilon \). Finally, \( g \) is the atom/ QDM-cavity coupling. Again, we can solve the master equation in the steady state regime \( (d\rho/dt = 0) \) and then we can derive the main optical properties of the system. We do this numerically by properly truncating the Hilbert space of the cavity mode and then using QuTip algorithms. Going back to Fig. 2(b), we note that the populations of the system does not present a substantial difference when we have null (QDM) or non-null (atom) \( \Gamma_{23} \) for the

Figure 3. Linear and nonlinear optical susceptibilities. In panels (a–f) and from (g–l) we plot the imaginary [real] part of \( \chi^{(n)} \) \((n = 1, 3, 5)\) for the atomic/quantum dot molecule systems in two different regimes of parameters, i.e., EIT (left panels) and CPT (right panels), considering the same set of parameters as in Fig. 2.
EIT regime of parameters ($\Theta \gg \Omega_p$). However, the populations in the EIT regime ($\Omega_p \gg \Theta$) are strongly dependent on $\Gamma_{32}$, as we see in Fig. 2(d): for $\Gamma_{32} = 0$ (QDM) $P_0 \approx 1$ and $P_2 \approx 0$ for all values of $\Delta_p$ except for $\Delta_p \approx 0$, i.e., exactly on the dark state resonance. This means that the linewidth of the dark state for the QDM case can be narrower than the atomic case. When we place the atom/QDM inside a cavity, its transmission will be strongly affected by this difference of populations (for $\Gamma_{32}$ null and non-null cases). In Fig. 4 we plot the normalized cavity transmission ($|\theta|/\text{max}(|\theta|)$, with $n = \{a^\dagger a\}$) of the atom/QDM-cavity systems, either in the EIT or in the CPT regimes. In both cases we have considered $\kappa = \Gamma$. Again, for the atom we have considered $\Gamma_{31} = \Gamma_{32} = 0.5\Gamma$ and for the QDM, $\Gamma_{31} = \Gamma$ and $\Gamma_{32} = 0$. The other parameters are $\kappa = \Gamma$, $\gamma = 5\kappa$, $\varepsilon = \sqrt{0.01}\kappa$, and $\Theta = 1.0\kappa$ for the EIT and $\Theta = 0.1\kappa$ for the CPT regimes.

As it happens in free space, when $\Theta \rightarrow 0$, there will be an effective decay from level $|1\rangle$ to $|2\rangle$, whose effective decay rate is $R_3 \Gamma_{32}$, which modifies considerably the dynamics of the system when $\Gamma_{32} = 0$ (atoms). This is indeed the case, as we can see in the inset of Fig. 4(c), where we plot the transmission of the QDM-cavity system with an additional effective decay from level $|1\rangle$ to $|2\rangle$ (decay rate $R_3 \Gamma_{32}/2$). When $\Theta \rightarrow 0$ we have a two-level atom interacting with a driven cavity mode. In this case, and considering the probe field close to resonance (around the EIT peak) we have $\Delta (\sigma_{31} - \sigma_{12}) = -n_0/(n + n_0)$, with $n_0 = \Gamma_3/8g^2$ and $n = |\alpha|^2 = \sum(n + n_0 + 2n_0)^2\Gamma_3$, being $C = 2g^2/\kappa \Gamma_3$ the cooperativity. In the limit of weak driving field ($\varepsilon \rightarrow 0$, which implies $n \ll n_0$) and large cooperativity ($C \gg 1$) we obtain $P_3 = 1/2(1 + \{\sigma_{12} - \sigma_{21}\}) \approx |\varepsilon/2g|^2$, resulting in an effective decay rate from level $|1\rangle$ to $|2\rangle$ given by $R_{3/2} = |\varepsilon/2g|^2 \Gamma_3$. Including this dissipation channel in the master equation of the QDM-cavity system we recover approximately the atom–cavity dynamics (around the EIT peak), as we see in the inset of Fig. 4(c).

As we see in Fig. 4(c), when we decrease $\Omega_c$ ($T_c$, i.e., in the CPT regime, the transmission around $\Delta_p = 0$ increases for the atomic system while for the QDM system it remains non-null only exactly on the dark state resonance, i.e., at $\Delta_p = 0$. This happens because the population of the ground state $|2\rangle$ increases due to the presence of the decay channel associated to $\Gamma_{32}$ as $\Omega_c \rightarrow 0$, making the atom-cavity system transparent to the probe field (empty cavity situation). On the other hand, in the QDM system, i.e., for $\Gamma_{32} = 0$, in the limit $T_c \rightarrow 0$ we end up with a perfect two-level system, which presents null transmission at $\Delta_p = 0$ and strong coupling regime ($\varepsilon \gg \kappa, \Gamma_3$). In this way, here we have an interesting difference between atomic and QDM behaviors: while the atomic system reaches an empty cavity transmission profile when $\Omega_c \rightarrow 0$, the QDM system presents a very narrow transmission peak when $T_c \rightarrow 0$. In Fig. 5 we plot the full width at half maximum (FWHM) of the dark state resonance for the atomic and QDM systems as a function of $\Theta$ ($= \Omega_c$ or $T_c$). The background color represents approximately the different regimes: CPT (darker region, on the left), EIT (intermediate region), and Außer–Townes splitting (clearer region, on the right). We note that the FWHM reaches a minimum value for the atomic system and then starts increasing as the population of the ground state $|2\rangle$ increases (for $\Omega_c \rightarrow 0$). We have started with very small values of $\Theta$, i.e., $\Theta_{\text{min}} = 0.001\kappa$ since for $\Theta = 0$ the QDM reduces to a two-level
system and then it is not possible to define FWHM). The FWHM is also dependent on the strength of the probe field (\(\varepsilon\)), as we see in 5(a) to (d). For very small mean number of photons inside the cavity, the probability of excitation of the atom/QDM is also very small. For instance, for maximum average number of photons 0.01, Fig. 5(a), the minimum FWHM for atom is very close to that for QDM. However, the difference between atom and QDM increases when we increase the average number of photons. Increasing \(\varepsilon\) we get a higher probability of having two (or more) photons inside the cavity. But, as we are considering only a single atom/QDM interacting with the cavity mode, it can absorb only a single photon from the probe field. In this way, the minimum FWHM also depends on the number of atoms/QDMs inside the cavity. Thus, considering the application in cavity-linewidth narrowing based on cavity EIT as proposed in24 and experimentally verified by H. Wang et al.25, our results show that QDM allows to reach FWHM narrower than atomic systems in the limit of \(\Theta \to 0\), thus being more attractive for this kind of application. As we see in Fig. 5(b), the minimum FWHM for atom becomes 35% broader than the minimum FWHM for QDM system. For stronger values of \(g\) the minimum FWHM for atomic and QDM systems becomes closer.

Conclusion

We have investigated the influence of the asymmetric decay of the excited state of three-level systems in \(\Lambda\)-configuration on the EIT and CPT processes. When the decay rate \(\Gamma_{31} \gg \Gamma_{32}\), which can be found in Quantum Dot Molecule (where \(\Gamma_{32} = 0\)), the nonlinear susceptibilities \(\chi(3)\) or \(\chi(5)\) is much smaller (in absolute values) than in the case where \(\Gamma_{32} \approx \Gamma_{31}\), which is usually the case for atomic systems. Thus, the high nonlinear effects present in EIT or CPT experiments are strongly related to the decay channel \(\Gamma_{32}\), which is associated to the transition coupled by the control field. On the other hand, non-null \(\Gamma_{32}\) implies in high population of the system in the state \(|2\rangle\) in the limit of \(\Theta \ll \Omega_p\). When this system is placed inside a cavity, this results in an empty cavity situation, increasing its transmission. On the order hand, for \(\Gamma_{32} = 0\) we end up with a perfect two-level system resonantly coupled to a cavity mode, which presents null transmission when the probe field is resonant with the cavity mode and in the strong atom/QDM-cavity coupling. Thus, only exactly on resonance we have the dark state, implying a very narrow transmission peak for the QDM when compared with atomic systems. In this way, we hope this work can be useful for studies on nonlinear effects in EIT or CPT processes and future applications in cavity-linewidth narrowing.

Figure 5. Full Width at Half Maximum (FWHM) of the dark state resonance. FWHM for the atomic (black solid line) and QDM (red dotted line) systems as a function of \(\Theta (= \Omega_c / T_p)\). Here assumed \(\Gamma_1 = \Gamma_{31} = 10^{-3}\Gamma\) and the other parameters are the same as those used in Fig. 4, except for \(\varepsilon\), which implies different maximum average number of photons inside the cavity \((\langle n \rangle_{\text{max}} = \sqrt{1 / \kappa})\). (a) \(\varepsilon = \sqrt{0.01} \kappa\), (b) \(\varepsilon = \sqrt{0.1} \kappa\), (c) \(\varepsilon = \sqrt{0.3} \kappa\), and (d) \(\varepsilon = \sqrt{1.0} \kappa\). In some cases, the minimum FWHM for QDM becomes 10% narrower than the minimum FWHM for atomic system.

Acknowledgements
C.J.V.-B. and H. S. Borges acknowledge support from CNPq and São Paulo Research Foundation (FAPESP), grant 2013/04162-5 and grant 2014/12740-1, and the Brazilian National Institute of Science and Technology for Quantum Information (INCT-IQ). M.H. O. acknowledges support from CNPq.

Author Contributions
C.J.V.B. conceived the project, produced the codes for the simulation and wrote the manuscript. H.S.B. obtained the analytical results, helped with the simulations and edited the figures. M.H.O. helped with the simulations and explanations of the results, reviewed the text and gave the final approval for the publication of this paper.
