Abstract: In this work, optical, including photoluminescence and photosensitivity, characteristics of micrometer-sized flexible \(n\) (\(p\))–InSe/\(\text{In}_2\text{O}_3\) heterojunctions, obtained by heat treatment of single-crystalline InSe plates doped with (0.5 at.\%) Cd (Sn), in a water-vapor- and oxygen-enriched atmosphere, are investigated. The Raman spectrum of In\(_2\)O\(_3\) layers on an InSe:Sn substrate, in the wavelength range of 105–700 cm\(^{-1}\), contains the vibration band characteristic of the cubic (bcc-In\(_2\)O\(_3\)) phase. As revealed by EDX spectra, the In\(_2\)O\(_3\) layer, ~2 \(\mu\)m thick, formed on InSe:Sn contains an ~18\% excess of atomic oxygen. The absorption edge of InSe:Sn (Cd)/In\(_2\)O\(_3\) structures was studied by ultraviolet reflectance spectroscopy and found to be 3.57 eV and ~3.67 eV for InSe:Sn and InSe:Sn substrates, respectively. By photoluminescence analysis, the influence of doping impurities on the emission bands of In\(_2\)O\(_3\):Sn (Cd) was revealed and the energies of dopant-induced and oxygen-induced levels created by diffusion into the InSe layer from the InSe/In\(_2\)O\(_3\) interface were determined. The \(n\) (\(p\))–InSe/In\(_2\)O\(_3\) structures display a significantly wide spectral range of photosensitivity (1.2–4.0 eV), from ultraviolet to near infrared. The influence of Cd and Sn concentrations on the photosensitivity and recombination of nonequilibrium charge carriers in \(n\) (\(p\))–InSe layers from the heterojunction interface was also studied. The as-obtained nanosized InSe/In\(_2\)O\(_3\) structures are suitable for optoelectronic applications.

Keywords: chalcogenides; heterojunctions; thin films; single crystals; optical properties; photoluminescence; photosensitivity

1. Introduction

Indium monoselenide (InSe) is a typical representative of group III–VI layered materials (In and Ga monochalcogenides). Its single crystals are comprised of elementary stratified Se–In–In–Se packages, bound by van der Waals forces, much weaker than those between four monoatomic sheets inside a package, corresponding to an ionic-covalent (predominant) bonding [1]. This allows displacement of neighboring packages relative to each other, which explains InSe polytypism and flexibility.

Being an \(n\)-type material with a room-temperature direct band gap of about 1.3 eV and an indirect one of 1.26 eV, InSe is considered, along with other classes of narrow-gap semiconductors, as a promising material for solar energy applications [2,3]. As a typical
feature of InSe and other lamellar III–VI semiconductors (GaS, GaSe, GaTe, etc.), at the interface between stratified chalcogen–metal–metal–chalcogen packages, the valence bonds of chalcogens are practically completely compensated. This leads to a low surface-state density (∼10^{10} \text{ cm}^{-2}) and a low recombination rate of nonequilibrium charge carriers, which, together with a high absorption coefficient near the fundamental absorption edge, are requirements for broadband photosensitivity and high energy conversion efficiency of devices based on these materials.

As recent research has shown, by various technological procedures and, especially, by heat treatment in air, at temperatures below the melting point of semiconductor material, thin films of In$_2$O$_3$ and Ga$_2$O$_3$ oxides are formed on the surface of InSe and GaSe lamellae, respectively [4–6]. Indium (In$_2$O$_3$) and gallium (Ga$_2$O$_3$) native oxides are n-type semiconductors with a wide band gap, of 3.7 eV and 4.8 eV, respectively, extensively studied due to their wide range of technological applications, especially as electrodes in solar cells and in various optoelectronic devices [7,8].

An important role in the operation of photovoltaic devices is played by their surface reflection capacity. The refractive index of In$_2$O$_3$ and InSe in the visible–near infrared (vis–NIR) range is 1.9–2.0 and 2.9–3.0, respectively. Thus, the normal-incidence reflection coefficient for the surface of the In$_2$O$_3$ layer is ∼9.6–11%. At the same time, the InSe/In$_2$O$_3$ pair, for certain thicknesses of the In$_2$O$_3$ layer, is able to perform an anti-reflective function (reflection factor ≈ 0) over a wide spectral range. These properties have led to various developments in optoelectronics based on lamellar semiconductors and structures with n−In$_2$O$_3$ as an optical transparent electrode [9,10]. The rapid progress in modern optoelectronic technologies has driven the development of new low-dimensional materials with unusual properties (nanowires, nanolamellae) [11], as well as of devices based on them, especially flexible electronic devices, various bio-integrated devices, and many others [12–14]. According to recent literature (including the references mentioned above), researchers’ attention is currently focused on the development of ultraviolet optoelectronic devices (UV-C) with a narrow photosensitivity band in the UV region, including the “solar blind” range (solar radiation that is strongly absorbed and cannot reach the earth’s surface) [15,16]. These (solar blind) devices find application in fire alarm/detection systems, missile approach warning systems, biomedical analyses, astrophysics studies, etc. [17].

In this paper, we investigate the chemical composition and optical properties, including photoluminescence (PL) and photosensitivity, of n−In$_2$O$_3$/p−InSe: Cd and n−In$_2$O$_3$/n−InSe:Cd heterostructures obtained by the heat treatment of n−InSe:Sn and p−InSe: Cd plates in open air at a temperature of ∼600 °C. The ultimate goal of these studies is to develop flexible photoelectric devices with broadband photosensitivity.

2. Materials and Methods

To obtain the n−In$_2$O$_3$/p−InSe and n$^+$−In$_2$O$_3$/n−InSe structures, single-crystalline plates of InSe doped with 0.5 at.% Cd (to get p−InSe) and 0.5 at.% Sn (n−InSe), respectively, were used. Cadmium- and Sn-doped InSe single crystals were grown by the Bridgman–Stockbarger technique. The primary InSe: Cd and InSe: Sn compounds were synthesized from component elements, In (5N) and Se (5N), which were taken in stoichiometric quantities. The respective amounts of ln and Se, along with chemical elements Cd (5N) and Sn (5N), in proportions of 0.5 at.%, were introduced into quartz ampoules.

Electron and hole concentrations in n−InSe and p−InSe single crystals, at room temperature, determined from Hall effect measurements, were found to be of (4–6) × 10^{16} \text{ cm}^{-3} and 8 × 10^{13} \text{ cm}^{-3}, respectively. The preparation technology of n (p)−InSe lamellae and n (p)−InSe/In$_2$O$_3$ structures is described in [5].

Micro-Raman spectra were recorded using a WITec RA300 microscope (excitation wavelength of 532 nm). The reflection spectra in the UV region were recorded with a Specord M-40 spectrophotometer with a spectral energy resolution of 0.5 meV, equipped with accessories for reflectance measurements at an incidence angle ≤5°. The wavelength-modulated reflection spectra were recorded with spectrophotometric equipment based
on an MDR-2 type monochromator with 1200/600 mm\(^{-1}\) diffraction grating, in which one of the flat mirrors was replaced with a vibrating mirror made of Al, deposited on a 120-\(\mu\)m-thick Si plate with a surface area of \(\sim 30\text{ cm}^2\). The vibration frequency of the mirror was 22 Hz. The wavelength resolution provided by monochromator was \(\Delta \lambda = 2.5\text{ Å}\).

Photoluminescence and photosensitivity spectra were registered by means of photometric equipment, including an MDR-2 monochromator, equipped with a photomultiplier with a multi-alkali [(Na2K)Sb + Cs] photocathode with a quartz window. A quartz tungsten halogen lamp with a power of 150 W was used as the excitation source of the photocurrent in the examined structures (InSe:Cd and InSe:Sn)/\(\text{In}_2\text{O}_3\). The temperature of the W filament was \(\sim 3300\text{ K}\).

The photosensitivity of (InSe:Cd, InSe:Sn)/native oxide structures was excited with monochromatic radiation provided by a DRS-500 filtered mercury lamp (wavelength \(\lambda = 546\) nm), while PL excitation was performed using a \(\text{N}_2\) laser (\(\lambda = 334\) nm) and an MRL-637 red solid-state laser with a 100 mW output power. The intensity of the laser exciting radiation was attenuated using neutral density filters with thin Pt films deposited onto amorphous quartz plates (molten \(\text{SiO}_2\)).

The photoresponse of \(p-\text{InSe:Cd/}n-\text{In}_2\text{O}_3\) heterojunctions upon bending at an angle of 15\(^\circ\), in the plane perpendicular to the sample surface, was recorded on a structure formed on a plate of \(p-\text{InSe}\) doped with 0.5 at.% Cd, with a thickness of 28 \(\mu\m\). At the same time, a photoresistor was made based on an InSe:Cd plate with a thickness of 24 \(\mu\m\) of the same material. Thin In films were used as electrodes. The distance between them was 6 mm, while the surface area was equal to \(\sim 30\text{ mm}^2\). The thickness of the plates was calculated from the interference fringes of the transmission spectrum at wavelengths of 5–15 \(\mu\m\). The dependence of the photocurrent on the sample illumination using a (637 nm and 2 mW) laser radiation was studied. The beam density was \(\sim 1.5 \times 10^{16}\) photons cm\(^{-2}\).

3. Results and Discussion

By heat treatment in air, for 6–12 h, at a temperature of 600 °C, of InSe lamellae, specially undoped and doped with Sn and Cd, their surface is covered with a purple-blue \(\text{In}_2\text{O}_3\) layer, displaying a poor diffuse reflection. The surface morphology of these layers was studied in [18]. The performed scanning electron microscopy (SEM) inspection revealed that the \(\text{In}_2\text{O}_3\) layer is composed of nanowires and nanoribbons, the length of which is tens of nanometers [5].

The X-ray diffraction (XRD) patterns of the materials obtained by heat treatment, in air, of plates with a thickness of 10–30 \(\mu\m\) contain intense diffraction lines of the native oxide (\(\text{In}_2\text{O}_3\)), together with lines of a much lower intensity of the primary material (InSe). Valuable information on the structure and chemical composition of layers formed on semiconductor and dielectric surfaces can be obtained from X-ray photoelectron spectroscopy (XPS) and energy dispersive X-ray spectroscopy (EDX) analyses [19,20]. These surface analysis techniques are based on the fact that the binding energy of atom inner shell electrons varies depending on the chemical state of the neighboring atoms. The higher the electronegativity of the neighboring atoms, the higher the ionization energy of the inner shells. Although the energy resolution of EDX spectroscopy is lower than that of XPS and auger electron spectroscopy (AES), the EDX analysis can still be used to determine the elemental composition of thin metal (Ga, Zn, In) oxide layers [18,21–24].

Figure 1a shows the SEM micrograph for the region in close vicinity of the edge of the InSe:Cd plate (thickness 180 \(\mu\m\)), heat-treated in air at 600 °C for 6 h. As can be clearly seen from this image, cracks and micro-defects are present on the surface oxide layer of InSe:Cd plates. The elemental composition of the layer formed on the plate surface was determined by the intensity of the characteristic lines in the EDX spectrum (Figure 1b).

As can be seen from this figure, the layer of material penetrated by the electron beam with an energy of 20 keV contains indium and oxygen. \(\text{SiO}_2\) and \(\text{InAs}\) were used as standards for determining the concentration of O and In atoms. Their concentrations (Figure 1b) were found to be 22.45 wt.% and 67.51 at.% for O (K) and 77.55 wt.% and
32.49 at.% for In (L). If it is admitted that all the In atoms form the compound In$_2$O$_3$, then the layer of analyzed material contains a surplus of ~16% atomic oxygen.

![SEM image](image1.png)

**Figure 1.** SEM image (a) and the EDX spectrum (b) of the In$_2$O$_3$ layer formed on the surface of the InSe:Sn (0.5 at.% Cd) plate.

In [24], nanostructured In$_2$O$_3$ (in the form of nanowires and nanoprisms) was obtained by the calcination of In(OH)$_3$ micro-crystallites at 350 °C for 4 h. The In/O concentration ratio was found to be 2/3, which corresponds to the stoichiometric composition In$_2$O$_3$. One can admit that the surplus of oxygen atoms in the In$_2$O$_3$ layer on the InSe substrate is determined by the high oxygen absorption capacity (from air) of the In$_2$O$_3$ nanowires/nanoprisms formed at the temperature of 600 °C.

The depth ($d$) of the In$_2$O$_3$ layer penetrated by the electron beam with energy $E_0 = 20$ keV can be approximated using the Kanaya–Okayama empirical formula [25]:

$$d \, (\mu m) = \frac{0.0276}{\rho} \frac{A}{Z^{0.89}} E_0^{1.67},$$

where $Z$ is the atomic number, $A$ denotes the mass number, and $\rho$ is the density (g/cm$^3$). For $\rho = 7.2$ g/cm$^3$, $Z = 122$, $A = 278$, and $E_0 = 20$ keV, $d = 2.2$ µm.

Additional information concerning the chemical composition of the layer formed on the surface of the InSe:Sn plates was obtained from the analysis of Raman spectra (Figure 2). In the wavenumber range of 60–700 cm$^{-1}$, eight vibration bands are well emphasized, of which four intense bands are located at low frequencies, 100–300 cm$^{-1}$. In refs. [26–28], the peak at 135 cm$^{-1}$ is associated with the In–O vibrations in the InO$_6$ octahedron, while the peak located at 306 cm$^{-1}$ is attributed to the stretching vibrations of the octahedra. The 501 cm$^{-1}$ and 627 cm$^{-1}$ high-frequency vibration modes are interpreted in [29] as stretching vibrations in the InO$_6$ octahedra. As can be seen from Figure 2, in the spectral range of 340–450 cm$^{-1}$, some vibration bands are missing and, instead, an intense peak at 250 cm$^{-1}$ is present. In the micro- and nanostructured In$_2$O$_3$ layers with oxygen vacancies, a low-intensity Raman peak centered at 306 cm$^{-1}$ is clearly emphasized [30]. The presence of the 250 cm$^{-1}$ peak for the In$_2$O$_3$ layers on the InSe substrate may be caused by the excess oxygen in it.

In order to further study the chemical composition of the layer formed on the surface of the InSe:Sn plate, the Raman peak positions (in cm$^{-1}$) from Figure 2 are summarized in Table 1. For comparison, the vibration frequencies of the rhombohedral InSe lattice [31], as well as those of the body-centered cubic In$_2$O$_3$ in the form of nanowires [32] and nanocubes [30], were also included. As can be seen from this table, the intense bands with the maxima at 110, 135, 231, 306, and 627 cm$^{-1}$ (Figure 2) are in good agreement with the Raman frequencies in the ensembles of In$_2$O$_3$ nanoformations, identified in the works [30,32] as vibrations in cubic In$_2$O$_3$ crystallites. The good correlation between the
sets of vibration modes of the In$_2$O$_3$ layers (Table 1, column 2) and those of the bulk In$_2$O$_3$

single crystals (column 6) indicates that both In$_2$O$_3$ nanowires and crystallites are present
in the layer formed on the surface of the InSe:Sn plate. At the same time, the low-intensity
bands positioned at 225, 475, 540, and 635 cm$^{-1}$ (Table 1, column 7) are emphasized in
the Raman spectrum, which have been identified in [33] as surface vibration modes in
nanocrystalline SnO$_2$. The 1–2 cm$^{-1}$ difference between the Raman peak frequencies in
the In$_2$O$_3$ layers formed on the surface of the InSe:Sn plates and those in nanowires and
nanocubes can be caused by the nature and size of the In$_2$O$_3$ nanoformations.

and InSe.

Figure 3 shows the reflection spectra for an incidence angle of $\sim 5^\circ$, in the region of the
fundamental absorption edge of In$_2$O$_3$ layers on $n$- and $p$-InSe substrates.
The reflection factor, \( R \), at normal incidence, for the separation surface between two distinct optical media depends on the relative refractive and extinction indices, \( n_r \) and \( k_r \), respectively, by means of the relation [34]:

\[
R = \frac{(n_r - 1)^2 + k_r^2}{(n_r + 1)^2 + k_r^2}.
\]

In the optical transparency region (\( \lambda > 380 \text{ nm} \)), the inequality \( k_r^2 \ll (n_r - 1)^2 \) is valid so that the term \( k_r^2 \) can be neglected in both the numerator and the denominator of the above equation [35,36]. The refractive index of the \( \text{In}_2\text{O}_3 \) layer depends on the electron concentration and varies between 2.17 and 1.83 for concentrations in the range of \( 10^{19} < N_e < 10^{21} \text{ cm}^{-3} \) [37]. In the considered case, putting \( n_r \approx 2 \) in Equation (2), a reflection factor of \( \approx 11\% \) is obtained for the air/\( \text{In}_2\text{O}_3 \) interface.

As can be seen from Figure 3 (curves 1 and 2), in the vicinity of the fundamental absorption edge of \( \text{In}_2\text{O}_3 \) crystallites, an increase by 2–3\% in the reflectance can be observed together with an increasing wavelength. As can be seen from Figure 3 (curves 3 and 5), in the wavelength range of 300–360 nm, the reflection spectrum of the \( \text{In}_2\text{O}_3 \) layer on the undoped InSe substrate overlaps with that recorded for the \( \text{In}_2\text{O}_3 \) layer formed on the doped substrate with 0.5 at.\% Cd.

The linear region of the reflectance graphs for the \( \text{In}_2\text{O}_3 \) layer formed on InSe:Cd plates exhibits an ~15 nm redshift with respect to that formed on the surface of InSe:Sn plates. This displacement is clearly emphasized in the second derivative of the reflectance spectra, \( \frac{d^2R(\lambda)}{d\lambda^2} \).

The energy band gap in semiconductor materials can be suitably determined from modulated reflection spectra (by wavelength, electric field, temperature, etc.), considering the wavelength at which the function \( \frac{\Delta R}{R} (\lambda) \) passes through zero [38]. In Refs. [36,39], the direct and indirect band gaps are determined from the spectral analysis of the function \( \frac{\Delta R}{R\Delta \lambda} (\lambda) \) in van der Waals and III–VI (GaS, GaSe, InSe) crystals. Since the photon energy for which this function passes through zero cannot be accurately determined, the property of the second derivative \( \frac{d^2R(\lambda)}{d\lambda^2} \) to reach its maximum (a well-pronounced

Figure 3. Reflection spectra of the \( \text{In}_2\text{O}_3 \) layer on InSe:Sn (curve 1), InSe:Cd (curve 2), and undoped InSe (curve 5) substrates and their second derivatives with respect to wavelength (curves 3, 4, and 6, respectively).
peak) at a photon wavelength corresponding to the forbidden bandwidth was used. The analysis method for the particularities of the reflection spectra by means of the $d^2R(\lambda)/d\lambda^2$ function elaborated in [35] is widely applied in the analysis of the FTIR reflection spectra.

In Figure 3 (curves 3, 4, and 6), plots of the second derivative, $d^2R(\lambda)/d\lambda^2$, are also presented. The maxima of respective functions are positioned at 338 nm (3.69 eV) and 347.2 nm (3.57 eV) for the reflection spectra from the In$_2$O$_3$ layer on InSe:Sn, InSe:Cd, and undoped InSe substrates, respectively. In [40], it was established that the band gap of In$_2$O$_3$ layers increases from 3.55 to 3.80 eV with increasing concentration of free charge carriers, from $2.6 \times 10^{19}$ to $7.0 \times 10^{19}$ cm$^{-3}$. At the same time, the electron effective mass is also increasing (>0.8 $m_0$) with the electron concentration in In$_2$O$_3$ for $n \geq 10^{19}$ cm$^{-3}$ [41].

Indium oxide is an $n$-type semiconductor. Its doping with Sn contributes to the increase in the concentration of free charge carriers, while Cd as a dopant compensates the free charge carriers, thus decreasing the electron concentration in the conduction band (CB). One can consider that at low concentrations, Cd doping does not practically influence the optical band gap, $E_{g0}$ (Figure 3, curve 6). The direct band gap in a heavily doped semiconductor, $E_{g\text{rn}}$, is given, in virtue of the Burstein–Moss model (parabolic band approximation), by [42]:

$$E_{g\text{rn}} = E_{g0} + \frac{\hbar^2}{2m^*_{\text{c}}}(3\pi^2n)^{2/3},$$

where $E_{g0}$ is the band gap of the undoped material; $m^*_{\text{c}}$ denotes the reduced effective mass of charge carriers (1/$m^*_{\text{c}} = 1/m^*_v + 1/m^*_e$) [43], with $m^*_v$ and $m^*_e$ representing valence band (VB) and CB effective mass, respectively; $\hbar$ is the reduced Planck’s constant; and $n$ is the electron concentration. Since $m^*_{\text{c}} \geq m_0$ [44], one can consider $m^*_{\text{c}} = m^*_e$. If one admits that the optical band gap of In$_2$O$_3$ corresponds to that of the In$_2$O$_3$:Cd layer (3.57 eV), then from Equation (3), with $m^*_c = 0.2$ $m_0$ ($m_0$—electron mass) and $E_{g\text{rn}} = 3.69$ eV, the electron concentration in the surface native oxide layer of InSe:Sn plates can be determined and is found to be $2.8 \times 10^{19}$ cm$^{-3}$. The electron concentration in the thin In$_2$O$_3$:Sn layer, determined by the Hall effect and electrical conductivity measurements, varies between $1.3 \times 10^{19}$ and $1.5 \times 10^{21}$ cm$^{-3}$ [37].

The In$_2$O$_3$ layers formed on $n$–InSe:Sn and $p$–InSe:Cd substrates are materials displaying visible photoluminescence (Figure 4a). Under laser excitation (power density 20 mW/cm$^2$) corresponding to the fundamental absorption edge of the In$_2$O$_3$ nanocrystallite layer on a $p$–InSe:Cd substrate ($\lambda = 337.4$ nm (3.68 eV)), the PL spectrum (Figure 4a, curve 1) is composed of two intense bands with maxima at 440 nm (2.75 eV) and 590 nm (2.10 eV), and a low-intensity plateau located in the wavelength range of 370–400 nm, with the edge at ~380 nm (3.22 eV).

Photoluminescence of micro- and nanoformations in the visible region has been the subject of many papers, especially [21,24]. The PL spectra of In$_2$O$_3$ microcrystals cover the wavelength range of 340–500 nm, with maxima positioned at 436 nm and 447 nm, as well as a plateau at 386 nm [24]. At the same time, the PL spectrum of an ensemble of nanospheres, studied in [21], under 400 nm wavelength excitation, is composed of three bands, with peak intensities at 452, 473, and 544 nm, while at 370 nm excitation, the peak intensity of the first two bands changes, while the third band shifts to longer wavelengths by 33 nm. The structure of the PL spectrum and the energy position of the PL maxima depend on the excitation wavelength [21]. The complexity of these PL spectra in the purple–blue region is explained by different concentrations of oxygen vacancies in studied samples [21,24]. The orange–yellow PL band, with a maximum at 580–590 nm, has been observed in many papers in which different types of In$_2$O$_3$ nanoformations have been studied [18,45,46] and is attributed to radiative transitions from the deep oxygen-vacancy defect energy levels. It is known that In$_2$O$_3$, in various types of nanoformations, is a good gas (especially oxygen) absorber [47].
The PL spectrum of the In$_2$O$_3$ layer obtained by heat treatment in air, at 550 °C, for 6 h, of the undoped InSe plates (Figure 4a, curve 3) is analogous to the PL spectrum (curve 2) of the In$_2$O$_3$ layer on an InSe:Sn substrate; it consists of a weakly asymmetric band with the maximum at 391 nm (3.17 eV). This PL band also predominates in the spectra of In$_2$O$_3$ nanoparticle ensembles with sizes from units to tens of nanometers [30,48,49].

A narrow band with the maximum located at 388 nm is characteristic of the PL emission of the In$_2$O$_3$ nanowire layer [48]. A PL spectrum composed of a band located in the wavelength range of 350–440 nm was also obtained for In$_2$O$_3$ nanocubes. From the comparison of PL spectra of In$_2$O$_3$ layers obtained by heat treatment in air, at 550 °C, for 6 h, of undoped InSe and 0.5 at.% Cd (Sn)-doped InSe plates (Figure 4), it is clear that the structure of the PL spectra is determined not only by the size and shape of nanoformations and by oxygen vacancies but also by the Cd and Sn impurities, which contribute to the luminescent recombination mechanism in In$_2$O$_3$.

Figure 4b shows the PL spectra of undoped InSe single crystals (curve 4), InSe doped with 0.5 at.% Cd (curve 2) and Sn (curve 3), as well as the PL spectrum from the InSe:Cd/In$_2$O$_3$ interface (curve 1), under excitation with 532 nm (2.33 eV) laser radiation with a power density of 5 mW/cm$^2$. The PL spectrum of InSe crystals (curve 4) consists of a band with a weak asymmetric contour and the maximum at 1010 nm (1.28 eV), which correlates well with the optical band gap of InSe at room temperature [50]. Therefore, the PL of undoped InSe crystals is determined by the recombination of nonequilibrium charge carriers in the CB with the holes in the VB. The PL peak intensities of InSe single crystals doped with Sn and Cd are located at 1025 nm (1.210 eV) and 1047 nm (1.184 eV), respectively. These maxima exhibit a redshift, compared to the emission band of the undoped crystals, of ~18 meV and 44 meV, respectively. This displacement is likely due to the shift of CB and VB edges in these crystals. The PL band, at 77 K, of Sn-doped InSe single crystals is shifted toward lower energies by 18 meV, compared to that of undoped crystals [51].

The PL spectrum of the material of the interface layer from the InSe:Cd/In$_2$O$_3$ heterojunction (Figure 4b, curve 1) contains two bands with maxima located at 962 nm (1.287 eV) and 1003 nm (1.235 eV). These bands are shifted toward a high-energy region relative to the PL band of the primary compound (InSe:Cd) (Figure 4b, curve 2) with ~100 meV and 51 meV, respectively. Such a shift can be determined by the presence of different types of nanoformations in the InSe layer from the heterojunction interface. In [52], PL spectra of InSe thin films are provided, from which a blueshift of ~140 meV for film thicknesses smaller than 24 nm can be easily observed.
Figure 5 shows the spectral dependencies of photoresponse (PR) (photocurrent generated per unit of incident power and unit area of detector) as a function of photon energy for the isotypic structures $n$–InSe:Sn/$n^+$–In$_2$O$_3$ (curve 1) and $p$–InSe:Cd/$n$–In$_2$O$_3$ (curve 2).

![Figure 5: Photoresponse of $n^+$–In$_2$O$_3$/$n$–InSe:Sn (curve 1) and $n$–In$_2$O$_3$/$p$–InSe:Cd (curve 2) heterojunctions as a function of incident photon energy.](image)

The red PR threshold is determined by direct optical transitions in the InSe layer from the interface with In$_2$O$_3$. Since the In$_2$O$_3$ layer was formed by the oxidation of the $p$ ($n$)–InSe plates, the slow increase in PR together with incident photon energy indicates that at the InSe:Cd/In$_2$O$_3$ interface, no additional recombination centers of nonequilibrium charge carriers are formed. The mentioned structural features of InSe (and other group III–VI layered materials), together with high absorption coefficient $\alpha \geq 1/L$ ($L$ is the mean free path of charge carriers), determine the monotonous increase in the photoresponse in heterojunctions with its native oxide ($p$–InSe/In$_2$O$_3$) and structures based on gallium and indium monochalcogenides [53–55]. The abrupt drop in PR at energies higher than 3.65 eV (curve 2) is probably due to the absorption threshold of the In$_2$O$_3$ layer. Characteristic for heterojunctions formed by semiconductors of the same type is the narrow photoresponse band and the low open circuit voltage [56,57]. The decrease in PR of the $n$–InSe/$n^+$–In$_2$O$_3$ structures at energies over 1.90 eV can be determined by the increase in the absorption coefficient of the $n$–InSe:Sn layer and by the presence of an additional concentration of defects at the $n$–InSe/$n^+$–In$_2$O$_3$ interface.

The flexibility of the $n$–In$_2$O$_3$/$p$–InSe:Cd heterojunction and of the $p$–InSe:Cd photoreistor was studied by the repeated (cyclic) bending of the sample by 15°. The radius of curvature was determined by computational fitting of the image of the bent samples and was found to be equal to ~15 cm and 12 cm for the $n$–In$_2$O$_3$/$p$–InSe:Cd heterojunction and the $p$–InSe:Cd photoreistor, respectively.

Figure 6 shows the photoresponse in the $p$–InSe:Cd/$n$–In$_2$O$_3$ heterojunction and in the $p$–InSe:Cd lamellar photoreistor, depending on the number of bends in the newly manufactured devices (curves 1 and 3) and for repeated measurements after 48 h (curves 2 and 4). The decrease in the photocurrent at the first bending by 15° can be caused by the decrease in the number of incident photons. Although the monotonous decrease in the photocurrent, of $\leq 10\%$, together with the increasing number of deformations from 2 to 90, is probably determined by the formation of some defects in the $n$–In$_2$O$_3$ layer. As can be seen from the comparison of curves 2 and 4 with curves 1 and 3, 48 h after the first measurement cycle, the factors that influenced the decrease in the photocurrent as the number of bends increased are maintained.
Figure 6. Dependence of the photocurrent as a function of the number of bending cycles (N) at 15° for p–InSe:Cd/In2O3 heterojunctions (1, 2) and photoresistor based on the single-crystalline p–InSe:Cd plate (3, 4); curves 1 and 3 are the initial measurements; curves 2 and 4 are measurements repeated after 48 h.

Since the dependencies of the photocurrent on the number of bending cycles for heterojunctions and photoresistors are similar, we can state that the factors leading to the decrease in the photocurrent in these devices are characteristic for InSe:Cd plates. Obviously, upon bending, internal stresses are formed in the InSe layer, which can lead to a change in the forbidden bandwidth and, thus, in the photoresponse bandwidth. In works [58,59], the elastic constants and the pressure dependence of the energy band gap in the lamellar compounds GaS, GaSe, and InSe were studied, from which it can be seen that the compressive forces between the packages are slightly decreasing from GaSe to InSe, from $6.28 \times 10^{-10}$ to $4.8 \times 10^{-10}$ N m$^{-2}$ respectively, while the absorption edge slightly shifts toward higher energies as the pressure increases.

Consequently, one can state that bending by $\sim 15°$ will exert a weak influence on the PR bandwidth of the p–InSe:Cd/n–In2O3 heterojunctions. As can be seen from Figure 5, the photosensitivity band of these heterojunctions covers a broad spectral range, from 1.25 to 3.70 eV. The flexible photodetectors studied in works [13,14] show photosensitivity in the UV-C region (200–300) nm.

4. Conclusions

By heat treatment in air, at a temperature of 600 °C, of InSe single-crystalline plates doped with Cd and Sn, in a water-vapor- and oxygen-enriched atmosphere, In2O3 layers and p (n)–InSe/n–In2O3 structures can be obtained, displaying blue–orange PL and broadband photosensitivity. As Raman and EDX analyses show, the layer of material formed on the surface of InSe:Sn plates is comprised of the compound In2O3 with an excess of absorbed oxygen.

The band gap of the native oxide layer, determined by wavelength-modulated reflectance spectroscopy, is equal to 3.57 and 3.67 eV for the In2O3 layer formed by the heat treatment of single-crystalline InSe plates doped with Sn and Cd, respectively.

The In2O3 layer is a photoluminescent material in the visible range. The structure of its PL spectrum is determined by actual dopants: Cd in p–InSe:Cd/n–In2O3 and Sn in n–InSe:Sn/n$^+$–In2O3 structures.
The p-InSe/n-In$_2$O$_3$ heterojunctions and p-InSe:Cd photoresistors maintain their photosensitivity upon multiple bending cycles.

The relative photosensitivity band of p-InSe/n-In$_2$O$_3$ structures is determined by the fundamental absorption threshold of p-InSe and at higher energies, by that of In$_2$O$_3$.
