Abstract. Atmospheric $p$CO$_2$ is a critical component of the global carbon system and is considered to be the major control of Earth’s past, present, and future climate. Accurate and precise reconstructions of its concentration through geological time are therefore crucial to our understanding of the Earth system. Ice core records document $p$CO$_2$ for the past 800 kyr, but at no point during this interval were CO$_2$ levels higher than today. Interpretation of older $p$CO$_2$ has been hampered by discrepancies during some time intervals between two of the main ocean-based proxy methods used to reconstruct $p$CO$_2$: the carbon isotope fractionation that occurs during photosynthesis as recorded by haptophyte biomarkers (alkenones) and the boron isotope composition ($\delta^{11}$B) of foraminifer shells. Here, we present alkenone and $\delta^{11}$B-based $p$CO$_2$ reconstructions generated from the same samples from the Pliocene and across a Pleistocene glacial–interglacial cycle at Ocean Drilling Program (ODP) Site 999. We find a muted response to $p$CO$_2$ in the alkenone record compared to contemporaneous ice core and $\delta^{11}$B records, suggesting caution in the interpretation of alkenone-based records at low $p$CO$_2$ levels. This is possibly caused by the physiology of CO$_2$ uptake in the haptophytes. Our new understanding resolves some of the inconsistencies between the proxies and highlights that caution may be required when interpreting alkenone-based reconstructions of $p$CO$_2$.

1 Introduction

Understanding the absolute level and evolution of atmospheric $p$CO$_2$ through geological time is essential to our understanding of the Earth’s climate system. As both a fundamental first-order control and a contributor to multiple dynamic feedbacks, atmospheric $p$CO$_2$ is critical in setting Earth’s surface temperature (Lacis et al., 2010). Reconstructing $p$CO$_2$ evolution improves the understanding of both the mechanisms behind past climate change (Chalk et al., 2017) and provides novel constraints on climate sensitivities (PALAESENS, 2012; Martínez-Botí et al., 2015). This then allows ground truthing of our understanding the climate and the Earth system models that are used for predicting future climate change.

Over the past two decades, two common marine-based CO$_2$ proxies have emerged – alkenone-based $\epsilon_p$ values (CO$_2$(\textit{\epsilon}_p\textit{--alk})$), utilizing the carbon isotopic fractionation imparted during photosynthesis in a subgroup of haptophytes.
(Bidigare et al., 1997), and planktic foraminiferal δ^{11}B values (CO_{2\text{(δ^{11}B)plank}}), based on the pH control of boron speciation and isotopic fractionation in seawater (Hemming and Hanson, 1992). Multiple records of atmospheric pCO_{2} now exist for the Cenozoic from both methods, showing a broadly similar long-term trend from a high-CO_{2} greenhouse world of the early Cenozoic, when CO_{2} exceeded 400 μatm and may have been higher than 1000 μatm, to a low-CO_{2} bipolar glaciated world of the Late Pleistocene, when CO_{2} fell to below 300 μatm (Pagani et al., 2005, 2011; Pearson et al., 2009; Anagnostou et al., 2016; Foster et al., 2017; Sosdian et al., 2018; Super et al., 2018).

However, discrepancies have recently become apparent between both methods when applied to the last 20 Ma (Badger et al., 2013a, b). Specifically, the CO_{2(\text{δ}^{13}C)\text{alk}} reconstructions often suggest a lower magnitude of short-term pCO_{2} change compared to that from CO_{2(\text{δ}^{11}B)\text{plank}} (Badger et al., 2013b). Whilst this could be partially explained by mismatches between the sampling intervals, or by the influence of local surface water disequilibrium with the atmosphere with respect to CO_{2}, this discrepancy remains even for records generated from exactly the same sediment samples (Badger et al., 2013b vs. Martínez-Botí et al., 2015). Both the CO_{2(\text{δ}^{13}C)\text{alk}} and CO_{2(\text{δ}^{11}B)\text{plank}} have been used to estimate Earth system sensitivity in the Pliocene with differing results, with CO_{2(\text{δ}^{13}C)\text{alk}} suggesting a higher-than-present Earth system sensitivity Pliocene (7−10°C per CO_{2} doubling; Pagani et al., 2009), whilst CO_{2(\text{δ}^{11}B)\text{plank}} records sensitivity in line with our estimates for today (<5°C per CO_{2} doubling; Martínez-Botí et al., 2015). Although this is at least partly due to the different approaches used to calculate Earth system sensitivity in the two studies, it is also due to the differences in reconstructed pCO_{2} from the two approaches.

The CO_{2(\text{δ}^{13}C)\text{alk}} and CO_{2(\text{δ}^{11}B)\text{plank}} palaeobarometers are both based on mechanistic frameworks that have been calibrated in either the modern ocean or laboratory culture (Bidigare et al., 1997; Hemming and Hanson, 1992; Sanyal and Hemming, 1996; Pagani et al., 2002). These proxies can be further ground truthed in the recent geological past, when ice core records provide high-quality pCO_{2} data for the last 800 kyr (Bereiter et al., 2015 and Table 1). In previous work, both CO_{2(\text{δ}^{11}B)\text{plank}} (Sanyal et al., 1995; Hönsch and Hemming, 2005; Foster, 2008; Henehan et al., 2013; Foster and Sexton, 2014; Chalk et al., 2017) and CO_{2(\text{δ}^{13}C)\text{alk}} (Jasper and Hayes, 1990) have yielded pCO_{2} records similar in absolute value and amplitude of change to those derived from ice cores. However, the emerging discrepancies between the two methods (Badger et al., 2013a, b; Martínez-Botí et al., 2015) necessitate revisiting this validation, both between the two proxies and between marine proxy and ice core reconstructions.

The ice cores record the pCO_{2} of the Pleistocene glacial–interglacial cycles (Bereiter et al., 2015 and Table 1) and provide an opportunity for cross-calibrating proxy methods for determining atmospheric pCO_{2} in the geological archive (CO_{2(\text{δ}^{13}C)\text{alk}} and CO_{2(\text{δ}^{11}B)\text{plank}}) with the direct-CO_{2} measurements from the ice cores.

### Study site

Ocean Drilling Program (ODP) Site 999 is located in the Caribbean Sea (12°44.639′N, 78°44.360′W; 2838 m water depth; Fig. 1), has an orbitally calibrated age model, and has been used previously for CO_{2} reconstructions. Our temporal sampling resolution is ~6 kyr in the Pleistocene and ~9 kyr in the Pliocene. Although CO_{2(\text{δ}^{13}C)\text{alk}} and CO_{2(\text{δ}^{11}B)\text{plank}} are independent of one another in many respects, they both rely on assumptions about the equilibrium of surface seawater with the atmosphere with respect to CO_{2}, sea surface temperature, and on well-constrained age models, which can make direct comparison between records from different sites difficult. Here, we overcome these problems by producing CO_{2(\text{δ}^{13}C)\text{alk}} and CO_{2(\text{δ}^{11}B)\text{plank}} records from identical horizons in the same deep-ocean sediment core in (1) the late Pleistocene, permitting direct comparison to ice core data (Figs. 2a, 3), and (2) across the intensification of Northern Hemisphere glaciation (INHG) in the Pliocene (Seki et al., 2010; Martínez-Botí et al., 2015) (Fig. 2b).

In terms of CO_{2}, ODP Site 999 in the Caribbean Sea is today slightly out of equilibrium with the atmosphere, with surface waters a little oversaturated in CO_{2}, providing a small net source of CO_{2} to the atmosphere (~21 μatm; Takahashi et al., 2009). However, the site has been shown to be suitable for recording past changes in pCO_{2} (Foster, 2008; Foster and Sexton, 2014) and the air–sea equilibrium is not thought to have changed significantly from the Pliocene to today (see discussion in Bartoli et al., 2011). It is one of few sites where both alkenone and boron isotope records can be acquired given the good preservation of both foraminifera and organic matter (Foster, 2008; Badger et al., 2013b; Foster and Sexton, 2014; Martínez-Botí et al., 2015), and Pliocene records of both are available (Bartoli et al., 2011; Badger et al., 2013b; Martínez-Botí et al., 2015). It also has been demonstrated previously to record glacial–interglacial cycles of pH / CO_{2} (Foster, 2008; Henehan et al., 2013) and a Pleistocene CO_{2(\text{δ}^{11}B)\text{plank}} record from 0 to 250 ka has been recently published (Chalk et al., 2017).

### 2 Methods

#### 2.1 Alkenone isotopes

Our new alkenone-based CO_{2} record was calculated following Badger et al. (2013b), with modern-day phosphate used in the estimation of the “b” term, U_{2^{\text{NI}}}^2, temperatures, and modern-day salinity (35 psu). Samples were freeze dried, ground to a fine powder by hand, and extracted by Soxhlet apparatus using a dichloromethane (DCM) / methanol azeotrope (2 : 1, v/v) refluxing for 24 h. Total lipid extracts were divided into three fractions (F) by small (4 cm) sil-

Figure 1. Site map with locations of sites discussed in the text.

Alkenone identification was confirmed by gas chromatography (GC) mass spectrometry (ThermoQuest Trace MS, He carrier gas). Alkenone isotope analyses were performed using a Thermo Fisher Delta V connected via a GC isolink and ConFlo IV to a Trace GC. The GC oven was programmed to increase in temperature from 70 to 200°C at 20°C min⁻¹, then to 300°C at 6°C min⁻¹ and held isothermal for 25 min. Conversion to Vienna Pee Dee Belemnite (VPDB) was performed by reference to a laboratory standard gas of known δ¹³C and system performance was monitored using in-house fatty acid methyl ester and n-alkane standard mixtures of known isotopic composition. Long-term precision is approximately 0.3 ‰. To estimate sea surface temperature (SST), the F₂ fraction was also analysed by GC-flame ionization detection (Hewlett Packard 5890 Series II), and the GC oven was programmed to increase in temperature from 70 to 130°C at 20°C min⁻¹, then to 300°C at 4°C min⁻¹ and held isothermal for 25 min. An approximately 50 m, 0.32 mm internal diameter capillary column with a 0.12 μm thick dimethylpolysiloxane equivalent film. A H₂ carrier gas was used, and quantification was monitored using a hexadecan-2-ol standard added prior to column chromatography. System performance as monitored with an in-house fatty acid methyl ester standard. Alkenone ratios were converted to SST using the global core-top calibration of Müller et al. (1998). Although this is a linear calibration, our uncertainty treatment (see below) should encompass any minor deviation from linear as Uₚ approaches 1 (see also the discussion in Badger et al., 2013b). All alkenone analyses were carried out at the Bristol node of the NERC Life Sciences Mass Spectrometry Facility hosted by the Organic Geochemistry Unit, University of Bristol.

The alkenone isotope δ¹³C value is used to calculate the total carbon isotope fractionation that occurs during algal growth (εₚ). This isotopic fractionation has been shown to be controlled by [CO₂(aq)] (Eq. 1; Jasper and Hayes, 1990) which can then be converted to atmospheric CO₂ using Henry’s law.

\[ \varepsilon_p = \varepsilon_f - \frac{b}{[CO_2(aq)]} \] (1)

To calculate εₚ from alkenone δ¹³C values, the carbon isotopic composition of dissolved inorganic carbon (DIC) is required; this is calculated from planktic foraminiferal calcite δ¹³C, whilst the fractionation which occurs during carbon fixation (εᵣ) is assumed constant here. The b term is the sum of other physiological factors (such as growth rate, cell size, and light limitation) which is estimated from the relationship shown in the modern ocean between b and dissolved reactive phosphate [PO₄³⁻]. Further details of the treatment are detailed in Badger et al. (2013b).

Error bars in relevant figures are all 1 SD and based on a full Monte Carlo propagation (n = 10 000) of the following

www.clim-past.net/15/539/2019/ Clim. Past, 15, 539–554, 2019
uncertainties: ±2 °C and ±0.1 ‰ were applied to temperature and foraminiferal calcite δ13C (normal probability function (pdf); 2σ error) and ±2 and ±0.1 to salinity and [PO$_4^{3-}$], respectively (2σ; uniform pdf). Uncertainties on alkenone δ13C were estimated from replicate runs and calcite δ13C from repeat runs of an internal standard. Integrated analytical and calibration uncertainties for alkenone-based temperatures were estimated and conservative estimates of likely variation for salinity and [PO$_4^{3-}$] were used. An 11 % error on the slope of $b = a[\text{PO}_4^{3-}] + c$ was assumed, where $a = 116.96$ and $c = 81.41$ (Pagani et al., 1999).

For consistency with the CO$_2$($\delta^{11}B_{\text{plank}}$) record for this site, we now adjust for the disequilibrium by subtracting the present-day CO$_2$ surplus and thus recalculate the included values of Badger et al. (2013b) accordingly. SSTs for our new Pliocene data were published in Davis et al. (2013).

### 2.2 Boron isotopes

Boron isotope data were published in Chalk et al. (2017) and are from the same core samples as our alkenone measurements. *Globigerinoides ruber sensu stricto* (white, $n \sim 200$ individuals from 300 to 355 µm) samples were measured for boron isotope composition on Thermo Scientific Nectune multicollector inductively coupled plasma mass spectrometer (MC-ICP-MS) at the University of Southampton according to methods described elsewhere (Rae et al., 2011; Foster et al., 2013; Martínez-Botí et al., 2015). Analytical uncertainty is given by the external reproducibility of repeat analyses of Japanese Geological Survey Porites coral standard (JCP) at the University of Southampton following Henehan et al. (2013) and is typically <0.2 ‰ (at 95 % confidence). Metal element to calcium ratios (Li, Mg, B, Na, Al, Mn, Ba, Sr, Cd, U, Nd, and Fe) were analysed using an Thermo Element 2XR ICP-MS at the University of...
Southampton). Here, these data are used to assess adequacy of clay removal (Al/Ca < 100 μmol mol \(^{-1}\)) and to generate down core temperature. pH and CO\(_2\) were calculated using a Monte Carlo approach (uncertainties are 2 SD, \(n = 10,000\) replicates) using R (R Core Team, 2015). For pH, we use a boron isotopic composition of seawater of 39.6 ‰ (2 SD of 0.1; Foster et al., 2010) and experimentally determined isotopic fractionation factor (1.027; Klochko et al., 2006), as well as the species-specific calibration for \(G.\ ruber\) of Henehan et al. (2013) (also with incorporated uncertainties). For the CO\(_2\) calculations, we use a range of salinity (equal to that used in the CO\(_2(\varepsilon_p\text{–}\text{alk})\) calculations) and total alkalinity.
(TA) that encompasses the modern values (34–37 and 2100–2500 μM, respectively, both with a uniform rather than normal probability distribution. Temperature was determined using Mg/Ca of G. ruber following established methods; Delaney and Boyle, 1985; Evans and Müller, 2012). Mg/Ca SST of planktic foraminifera is used for CO$_2$($\delta^{13}$Bplank) and alkenone $U_{K^*}^{\delta}$ for CO$_2$(ε$_{\text{p}}$–alk) so that the carrier organisms for the CO$_2$ reconstruction and SST measurements match, ensuring the temperature measurement is coming from the appropriate part of the water column. Inorganic chemical constants were used from the seacarb package in R (Gattuso et al., 2008; Gibbs et al., 2013; Sheward et al., 1998), but some change in cell size is possible. Coccolith size is typically larger on larger cells, with that relationship being broadly consistent within a single taxonomic group where growth behaviour is broadly comparable (Henderiks, 2008; Gibbs et al., 2013; Sheward et al., 2017). Long-axis coccolith length measurements were therefore taken from 100 specimens of the family Noelaerhabdaceae per sample from standard smear slides. Specimens were imaged at 1500× magnification and measured using CellID software.

To investigate the potential influence of changing cell size on CO$_2$(ε$_{\text{p}}$–alk), Eq. (1) can be adapted:

$$\epsilon_p = \epsilon_f - \frac{b'}{[\text{CO}_2\text{aq}]}.$$  

with $b'$ calculated from using the volume to surface area ratio ($V$ : $SA$) of modern and fossil coccospheres (Eq. 3; Henderiks and Pagani, 2007):

$$b' = \frac{V : SA_{\text{fossil}}}{V : SA_{\text{Ehux}}}.$$  

$V$ : $SA_{\text{Ehux}}$ is 0.9 ± 0.1 μm in modern haptophytes (Popp et al., 1998) and $V$ : $SA_{\text{fossil}}$ can be estimated from lith size measurements (Eq. 4; Henderiks and Pagani, 2007):

$$D_{\text{cell}} = 0.55 + 0.88L_{\text{coccolith}}.$$  

### 2.4 Age model

For the 0–500 ka interval, we generated a detailed age model by tuning the planktic foraminifer (G. ruber) δ$^{13}$O record from Site 999 (at ∼ 0.5 to 2.0 kyr resolution) (Schmidt et al., 2006) to the LR04 benthic δ$^{18}$O stack (Lisiecki and Raymo, 2005) using the AnalySeries software (Paillard et al., 1996). The Pliocene portion of Site 999 is part the LR04 stack and that astronomically tuned age model is used here (Lisiecki and Raymo, 2005).

### 2.5 Bayesian exploration of CO$_2$(ε$_{\text{p}}$–alk) input variables

In order to examine the influence of the various input parameters for the calculation of $p$CO$_2$ from alkenone δ$^{13}$C values, we carry out a second set of Monte Carlo simulations ($n = 100,000$) with expanded uncertainty. In this case, we more fully explore uncertainty space using the following input uncertainties (at 95 % confidence or full range): SST (normal distribution, ±6°C), $\epsilon_f$ (uniform distribution, 24 to 28), $b$ (normal distribution, ±40), and CO$_2$ disequilibrium (20±20). These input distributions are our prior distributions. We then evaluate the CO$_2$ output for each alkenone sample against synchronous ice core $p$CO$_2$ and boron isotopic $p$CO$_2$ for the Pleistocene and Pliocene, respectively. By only selecting those simulated alkenone $p$CO$_2$ levels that agree with ice core or $p$CO$_2$($\delta^{13}$Bplank) (including associated uncertainties), we can reevaluate the input distributions (our posterior) and gain insights into the relative importance of each of the input variables in potentially driving the observed disagreement in $p$CO$_2$. Uncertainties in the $p$CO$_2$($\delta^{13}$Bplank) are as described above, and we apply an uncertainty of ±6 ppm (2 s) for the ice core $p$CO$_2$ record (Ahn et al., 2012).

### 3 Results and discussion

Alkenone and G. ruber δ$^{13}$C values (Fig. 3a, e) were used to calculate $\epsilon_p$ values (Fig. 3c, g). Alkenone δ$^{13}$C values are relatively stable through the Pleistocene portion of the record, varying between −24.5%ε and −23.2%ε. Values are slightly higher in the Pliocene, varying between −24.1%ε and −21.7%ε. G. ruber δ$^{13}$C values are relatively stable through the whole record, varying between 0.53%ε and 1.57%ε. These give rise to $\epsilon_p$ values which are similarly fairly stable, varying between 10.5%ε and 12.2%ε in the Pleistocene, and between 9.5%ε and 11.8%ε in the Pliocene. Our $U_{K^*}^{\delta}$ SST (Fig. 3c, g) record shows warmer temperatures in the Pliocene of around 27°C, with cooler temperatures recorded in the Pleistocene, with the coldest SST recorded in the glacial which is ∼ 2°C cooler than the interglacial. These records are combined (see methods section) to produce the $p$CO$_2$ record (Figs. 2, 3c, f), which shows largely stable and invariant values through both the Pliocene and Pleistocene portions of our record.
Published low temporal resolution Pliocene records from Site 999 (Seki et al., 2010), using both the CO$_2$(ε$_{p}$−alk) and CO$_2$(δ$^{11}$B$^{pl}$) palaeobarometers, show a $p$CO$_2$ decrease at $\sim$2.8 Ma. However, this agreement relies on correcting the CO$_2$(ε$_{p}$−alk) for changes in haptophyte cell size, which was based on a low temporal resolution lith size record (Seki et al., 2010). Changes in haptophyte cell size alter the volume to surface area ratio available for gaseous exchange and can therefore modify the fractionation recorded by CO$_2$(ε$_{p}$−alk) (Popp et al., 1998). Our new CO$_2$(ε$_{p}$−alk) record at Site 999 now spans 3.3–2.6 Ma at higher temporal resolution, supplementing data from Badger et al. (2013b). A lith size record has also been generated for the same samples used for CO$_2$(ε$_{p}$−alk) for 3.3–2.6 Ma (Davis et al., 2013). We find no evidence to support the change in lith size applied by Seki et al. (2010) with lith size (and hence cell size) remaining stable across the primary $p$CO$_2$ change at 2.8 Ma (Davis et al., 2013). Consequently, although our new CO$_2$(ε$_{p}$−alk) record is of higher resolution than that of Seki et al. (2010), we no longer have any evidence for the cell size shift at 2.7 Ma (Fig. 4).

We compare our record with the CO$_2$(δ$^{11}$B$^{pl}$) records of Martínez-Botí et al. (2015) in Fig. 2. With the cell size correction now removed, the decrease in CO$_2$(ε$_{p}$−alk) across the
InHNG, and the agreement of $\text{CO}_2(\varepsilon_{\text{alk}})$ with $\text{CO}_2(\delta^{11}\text{Bplank})$, both now disappear (red symbols, Fig. 2b). As such, $\text{CO}_2(\varepsilon_{\text{alk}})$ for this whole Pliocene interval (2.6–3.3 Ma) remains stable and low (mean $\text{CO}_2(\varepsilon_{\text{alk}}) = 251 \pm 13$; $1\sigma$ min = 228, max = 286 $\mu$atm), whereas $\text{CO}_2(\delta^{11}\text{Bplank})$ is on average higher and more variable (mean $\text{CO}_2(\delta^{11}\text{Bplank}) = 342 \pm 50$; $1\sigma$ min = 234, max = 452 $\mu$atm).

In the Pleistocene, our $\text{CO}_2(\varepsilon_{\text{alk}})$ record covers one complete glacial–interglacial (G-IG) cycle from 110 to 260 ka, encompassing MIS5–7, and the end of MIS8, and terminations II and III (open red diamonds; Fig. 2a). The $\text{CO}_2(\delta^{11}\text{Bplank})$ record of Chalk et al. (2017) covers two G-IG cycles from the late Holocene to MIS8 (open blue circles; Fig. 2a). $\delta^{11}\text{Bplank}$ closely tracks the rise and fall of $p\text{CO}_2$ derived from ice cores (Chalk et al., 2017), with $\text{CO}_2(\delta^{11}\text{Bplank})$ exhibiting similar values to atmospheric $\text{CO}_2$ within uncertainty (Fig. 2a), and with only small deviations from ice core $\text{CO}_2$ as a result of (i) the noise in the reconstruction and (ii) perhaps a small diagenetic effect on $\text{CO}_2(\delta^{11}\text{Bplank})$ relating to periods of carbonate dissolution in portions of the core which show high foraminiferal fragmentation (e.g., MIS5d; Schmidt et al., 2006).

In contrast, $\text{CO}_2(\varepsilon_{\text{alk}})$ is within error of the ice core data only during the interglacials when $\text{CO}_2$ partial pressures are similar to those of the pre-industrial era. Crucially, $\text{CO}_2(\varepsilon_{\text{alk}})$ clearly fails to record the lower $p\text{CO}_2$ of the glacial, remaining at around 260 $\mu$atm throughout (mean $\text{CO}_2(\varepsilon_{\text{alk}}) = 259 \pm 27$; Fig. 2a). This concentration of $p\text{CO}_2$ is also very close to that recorded by $\text{CO}_2(\varepsilon_{\text{alk}})$ in the Pliocene at this site (mean $\text{CO}_2(\varepsilon_{\text{alk}}) = 252 \pm 26$ $\mu$atm; Fig. 2). Similar alkenone behaviour has also been observed in another, albeit lower-resolution, record from ODP Site 925 (Zhang et al., 2013; Fig. 2), where the $\text{CO}_2(\varepsilon_{\text{alk}})$ remains unchanged during the Pleistocene (20–170 ka) and Pliocene.

Overall, these results suggest that, at least at these sites, the $\text{CO}_2(\delta^{11}\text{Bplank})$ Palaeobarometer does faithfully record atmospheric $\text{CO}_2$ change, whereas the $\text{CO}_2(\varepsilon_{\text{alk}})$ proxy is unable to reconstruct the low levels of atmospheric $\text{CO}_2$ during the glacial. This suggests that, in its present and frequently applied form, $\text{CO}_2(\varepsilon_{\text{alk}})$ is not accurately recording atmospheric $\text{CO}_2$, and this could explain the discrepancy between the Pliocene $\text{CO}_2(\varepsilon_{\text{alk}})$ and $\text{CO}_2(\delta^{11}\text{Bplank})$ records. We further evaluate this by using regression analysis between ice core and the paired-proxy data (Fig. 5). $\text{CO}_2(\delta^{11}\text{Bplank})$ levels are largely consistent with those determined from ice cores, clustering around the 1 : 1 line with a slope also close to 1 (0.95 ± 0.13) (Fig. 5a), whereas variance in $\text{CO}_2(\varepsilon_{\text{alk}})$ is strongly muted compared to that observed in the ice core data (Fig. 5b).

As both cell size (Popp et al., 1998) and growth rate (Biddigare et al., 1997) can modify $\delta^{13}\text{C}_{\text{alk}}$ via the $b$ term, we investigated whether either of these could explain the muted response of $\text{CO}_2(\varepsilon_{\text{alk}})$ to atmospheric $\text{CO}_2$. Haptophyte cell size can be estimated from their lith size, but as noted above, there is no evidence for significant changes in the Pliocene (Davis et al., 2013) nor is there evidence for any change across MIS5–8 (Fig. 4a). There is an overall reduction in mean lith size from the Pliocene to the Pleistocene (Fig. 4a, b), which could offset a long-term $p\text{CO}_2$ decline and thus explain the apparent lack of difference between Pliocene and Pleistocene $\text{CO}_2(\varepsilon_{\text{alk}})$ at Site 999 (Fig. 6). However, this longer-term reduction in lith size cannot explain the muted response to Pleistocene G-IG $\text{CO}_2$ change.

Growth rate is more difficult to reconstruct; most available proxy systems reconstruct phytoplankton or whole ecosys-

---

**Figure 5.** Regression analyses of proxy-based $p\text{CO}_2$ with ice core data (a) $\text{CO}_2(\delta^{11}\text{Bplank})$ (Chalk et al., 2017) and (b) $\text{CO}_2(\varepsilon_{\text{alk}})$ vs. ice core data (Bereiter et al., 2015 and Table 1) for MIS5–8, interpolated in the age domain. Regression lines (in red/blue) are linear fits with 68 % and 95 % confidence intervals, calculated by bootstrapping the uncertainties in proxy $p\text{CO}_2$ (Monte Carlo method described in the methods section). Uncertainty in the ice core values is by estimated by applying a 3000 uncertainty in the age model during interpolation. Uncertainty envelopes considering data points alone (no bootstrap) are solid lines, with $p_{\text{max}}$ regressions in the thicker, darker colours. A 1 : 1 line is shown in grey for comparison. Statistical calculations were performed in R (R Core Team, 2015).
Figure 6. Cell size corrections to $CO_2(\varepsilon_p - alk)$. Ornamentation is the same as Fig. 1, with the addition of cell-size-corrected $CO_2(\varepsilon_p - alk)$. The smaller liths than modern $E. huxleyii$ across all of our records mean that a direct application of the method of Henderiks and Pagani (2007) results in substantially lower $CO_2(\varepsilon_p - alk)$ throughout (open orange stars; c, d). As the main interest is in the effect of the Plio-Pleistocene change in cell size we observe, we adjusted the $b'$ term so that $CO_2(\varepsilon_p - alk)$ matched our uncorrected $CO_2(\varepsilon_p - alk)$ record during the last interglacial (filled orange stars; a, b).

Discussion

1. **Comparison with Other Studies**

   The failure of $CO_2(\varepsilon_p - alk)$ from these two sites to record the G-IG $pCO_2$ variation also necessitates reassessment of earlier $CO_2(\varepsilon_p - alk)$ studies that were able to reconstruct such changes. For instance, whilst Jasper and Hayes (1990) replicated the $CO_2$ change over the last 100 kyr of the Vostok ice core from Deep Sea Drilling Project (DSDP) Site 619 (Gulf of Mexico) and Bae et al. (2015) are able to replicate the ice core data at a site in the Sea of Japan, records from the Arabian Sea (Palmer et al., 2010), Angola Current (Andersen et al., 1999), and the equatorial Atlantic (Zhang et al., 2013) either fail to record ice core $CO_2$ or require additional corrections to do so (Fig. 7). It may also be that at some sites, such as at equatorial Pacific MANOP (Manganese Nodule Project) site C (Figs. 1, 7), these records represent changing air–sea disequilibrium (Jasper et al., 1994). Two of these studies interpreted their data using a different $\varepsilon_p$ relationship than later work; when these data are recalculated using the more recent model, the patterns remain unchanged (Fig. 7). What is more, in a global alkenone $\delta^{13}C$ calibration study (Pagani et al., 2002) aimed at replicating Holocene atmospheric conditions, it was noted that low-latitude (sub-tropical) sites perform poorly, consistent with our observations. Considering this present study and previously published work, five out of seven late Pleistocene alkenone $\delta^{13}C$
Our Bayesian approach allows us to explore the CO$_{2}$($\epsilon_{f}$-alk) proxy, as it was mathematically expressed by Bidigare et al. (1997) and subsequent authors, and test which variables may be responsible for causing the observed disagreement with the ice core and CO$_{2}$($\delta^{11}$B$_{\text{plank}}$) records given a largely invariant $\epsilon_{f}$ for the Pleistocene. Figure 8 illustrates the prior distributions of the input variables (blue) and an example posterior for the alkenone sample at 150 ka (red). As can be seen in this example, selecting only those simulations of CO$_{2}$($\epsilon_{f}$-alk) that overlap with the ice core CO$_{2}$ for this time interval shifts the distributions such that an agreement is found when $b$ is lower than the prior, $\epsilon_{f}$ tends to be higher than the prior, and SST and CO$_{2}$ disequilibrium are little different. Figure 9 shows the posterior median and 95 % distribution of $b$, $\epsilon_{f}$, and SST for all the samples from the Pleistocene and Pliocene in time series. Patterns that emerge are illustrated in Fig. 10, where a negative relationship between $p$CO$_{2}$ and posterior $\epsilon_{f}$ and a positive relationship between $p$CO$_{2}$ and posterior $b$ and SST are evident. For SST, it should also be noted that for the Pleistocene the posterior correlates well with the prior, while for the Pliocene it is significantly elevated (Fig. 10), perhaps suggesting a role for incorrect SST in driving some of the lack of Pliocene to Pleistocene change in CO$_{2}$($\epsilon_{f}$-alk) observed (Fig. 2). This SST change would however need to be substantial and go beyond the $\pm 2 \, ^{\circ}$C we include in our uncertainty propagation, and would also potentially influence CO$_{2}$($\delta^{11}$B$_{\text{plank}}$), further complicating this finding.

We recognize that the nature of the patterns we observe here is a function somewhat of the range used for each input term. The chosen ranges are however conservative, but realistic, assessments of the likely uncertainty associated with each term. For instance, $b\pm 40$ encompasses the residual scatter around the relationship between $b$ and [PO$_{4}$] described by Pagani et al. (2005). In addition to pointing towards a potential underestimate of Pliocene SST with the $U_{37}^{\prime}$ proxy at ODP 999, this Bayesian treatment supports the assertion that the current understanding of the CO$_{2}$($\epsilon_{f}$-alk) proxy is wanting and that the $b$ term may not in fact capture the scaling of the relevant physiological parameters or those that are truly important. In particular, it appears that the physiological parameters packaged in the $b$ term, and potentially the degree of fractionation upon fixation, $\epsilon_{f}$, are themselves a function of CO$_{2}$ or some parameter that correlates with CO$_{2}$ (e.g., temperature, nutrients, growth rate).

As noted above, mean lith size is significantly different for the Pliocene and Pleistocene. A comparison of our posterior $b$ and lith size does reveal a good correlation between these variables (Fig. 11: $r^{2} = 0.52$, $p \ll 0.01$), though this is largely, but not exclusively, a function of the mean change.
Figure 8. Example of the Bayesian treatment of the CO$_2$(ε$_p$−alk) proxy; the sample shown is 0.15 Ma from ODP Site 999. In all panels, the prior is shown in blue and the posterior in red. (a) The $b$ term, (b) $ε_f$, (c) the extent of CO$_2$ disequilibria, and (d) sea surface temperature.

Figure 9. Time series of priors and posteriors for the $b$ term (a, b), $ε_f$ (c, d), and SST (e, f). The Pleistocene is shown on the panels on the left and the Pliocene on the right. In panels (a–d), the mean of the prior distribution is shown as a thick black line. For the $b$ term, 95% of the input distribution is shown as a dotted line; for $ε_f$ the total range is shown. See Fig. 7 for examples of these distributions as probability functions. For SST (e, f), the prior is shown as red diamonds, with 95% of the distribution shown as the dashed lines. In all panels, the medians of the posterior distributions are shown as circles, with error bars encompassing 95% of the range.

across the Plio-Pleistocene. Importantly, the observed relationship between $b$ and lith size is very different from that described in Henderiks and Pagani (2007), suggesting that if lith size is important, our understanding, at least as laid out in Henderiks and Pagani (2007), is incorrect.

An alternative explanation however could be that the parameterization of physiological factors into the $b$ term model is simply flawed in general, or is at least lacking important components. The dominant species producing alkenones in this part of the Caribbean today is *Emiliania huxleyi* (Winter et al., 2002). *E. huxleyi* first appeared 290 kyr ago but did not become the dominant Noelaerhabdaceae until ∼ 82 ka, when it began to outcompete the closely related *Gephyrocapsa* spp., which in turn took over from *Reticulofenestra* in the late Pliocene (Raffi et al., 2006; Gradstein et al., 2012). Both our alkenone records are therefore a composite of closely related but distinct Noelaerhabdacean species, with neither record dominated by *E. huxleyi*. We cannot rule out that there could be physiological differences between the extant *E. huxleyi* species and the alkenone producers for our record. However, the Site 925 CO$_2$(ε$_p$−alk) record of the last glacial–interglacial cycle, which would have pri-
Figure 10. Relationships between CO$_2$ and (a) the $b$ term, (b) $\varepsilon_f$ and (c) SST. In each panel, the median of each posterior distribution is shown in red for the Pliocene and blue for the Pleistocene. Note that the CO$_2$ for each data point is either from the ice core or CO$_2$(δ$^{11}$Bplank) for the Pleistocene and Pliocene, respectively. The linear patterns that emerge here essentially represent the relationships of the Bidigare et al. (1997) approach given our otherwise invariant $\varepsilon_p$.

Figure 11. Comparison between the posterior distribution for the Pliocene (red circles) and Pleistocene (blue circles) and the lith size correction of Henderiks and Pagani (2007) (green dot–dash line).

Our data show that the classical application of the alkenone $p$CO$_2$ proxy fails to capture glacial–interglacial changes observed in the ice cores. With increased confidence in CO$_2$(δ$^{11}$Bplank) supplied by that proxy’s ability to capture Pleistocene $p$CO$_2$ variability, our data also suggest that the discrepancy between CO$_2$(δ$^{11}$Bplank) and CO$_2(\varepsilon_p$–alk) in the Pliocene may also be due to problems with CO$_2(\varepsilon_p$–alk).

Emerging insights into coccolithophore CO$_2$ allocation pathways and their sensitivity to CO$_2$ and temperature, in con-
junction with our inter-proxy comparisons, indicate that the long-standing CO$_2$(\(\epsilon_{\text{alk}}\)) proxy requires major revision and recalibration. If CCMs are preferentially more important for the alkenone palaeobarometer than growth rate, the muted alkenone palaeobarometer response may be limited to the low-CO$_2$ world of the Plio-Pleistocene and particularly in tropical waters where CO$_2$(aq) is especially low. By extension, this proxy (and interpretations based on it) likely retains utility at the higher CO$_2$ levels typical of the early Cenozoic (and at high latitudes where CO$_2$(aq) is high) where active carbon uptake is less likely (Zhang et al., 2013). This is especially true if haptophyte CCMs only evolved in the Late Miocene as a response to declining CO$_2$ levels (Bolton and Stoll, 2013). Regardless, the discrepancy between CO$_2$(\(\epsilon_{\text{alk}}\)) and ice core CO$_2$ records indicates that alkenone isotopes in several locations do not faithfully record atmospheric CO$_2$ at relatively low, Plio-Pleistocene-like CO$_2$ levels. Furthermore, the muted response of CO$_2$(\(\epsilon_{\text{alk}}\)) to [CO$_2$(aq)] at lower concentrations calls into question the underlying basis of the high climate sensitivities previously reconstructed using this method in the Plio-Pleistocene (Pagani et al., 2009). This, coupled with further evidence of the fidelity of CO$_2$(\(\delta^{13}\text{C}_{\text{Plank}}\)), at Site 999, suggests that the climate sensitivities derived from CO$_2$(\(\delta^{13}\text{C}_{\text{Plank}}\)) (which are consistent with climate models used both in palaeoclimate and future climate projections) are more accurate (Martínez-Botí et al., 2015).

**Data availability.** Data are archived on Pangaea (https://doi.pangaea.de/10.1594/PANGAEA.899353) (Badger et al., 2019).

**Supplement.** The supplement related to this article is available online at: https://doi.org/10.5194/cp-15-539-2019-supplement.

**Author contributions.** MPSB and GLF conceived the study (conceptualization). MPSB, TBC, and GLF designed the methodology, carried out data collection, and analysed the data (formal analysis, investigation, methodology). PRB, SJS, HP, and AM performed data collection. PFS finalized the age model (investigation). MPSB, TBC, and GLF designed the methodology. PRB, SJG, HP, and AM performed data collection and analysed the data (formal analysis, investigation, methodology). MPSB and GLF conceived the study (conceptualization). MPSB and GLF designed the methodology. MPSB, TBC, and GLF designed the methodology. MPSB, TBC, and GLF designed the methodology. MPSB, TBC, and GLF designed the methodology.
