BACKGROUND AND AIDS: Although there is much known about liver diseases, some aspects remain unclear, such as the nature of the differences between the diseases observed in newborn infants and those in adults. For example, how do newborns respond to duct epithelial cell injury? Do the stellate cells in newborns respond similarly to those in adults during biliary obstruction?

METHODS: Ninety newborn Wistar rats aged six days, weighing 8.0 – 13.9 g each, and 90 adult rats weighing 199.7 – 357.0 g each, were submitted to bile duct ligation. After surgery, they were randomly divided and sacrificed on the 3rd, 5th, 7th, 14th, 21st or 28th day post-bile duct ligation. Hepatic biopsies were obtained and immunohistochemical semi-quantification of desmin and α-SMA expression was performed in hepatic stellate cells and in myofibroblasts in the portal space, and between the portal space and the liver lobule.

RESULTS: Desmin expression in the myofibroblast cells post-bile duct ligation was higher in young rats, reaching its peak level in a shorter time when compared to the adult animals. The differences between the groups for α-SMA expression were less significant than for desmin.

CONCLUSIONS: These findings indicate that there is an increase in the number of collagen-producing myofibroblast cells in young animals, suggesting that there is more intense fibrosis in this population. This finding may explain why young animals with bile duct obstruction experience more intense portal fibrosis that is similar to the pathology observed in the livers of newborns with biliary atresia.

structural proteins of the intermediary filaments that are present in the cytoskeleton of smooth muscle cells and other cell types. Cassiman et al.\textsuperscript{17} described the presence of myofibroblast sub-populations in the liver parenchyma in three main areas: stellate cells in the lobule, the portal space and at the interface between the portal space and the liver lobule. In an experimental model of common bile duct ligation (BDL) with the induction of biliary-type portal fibrosis, these myofibroblast sub-populations can also be involved in the initial stages of fibrosis development, especially those populations located in the portal space and the interface zone.\textsuperscript{17,18}

Although much is known about cell injury and fibrosis induction as a result of liver diseases, some aspects remain unclear, such as the nature of the differences between the diseases seen in newborn infants, and those in older children and adults. Common bile duct ligation in rats is a classic experimental model for the study of biliary obstruction. However, the response of neonatal animals to bile duct ligation has yet to be completely understood, and few reports in the literature have focused on differences in the behavior of the liver in neonatal and adult animals.

In our previous investigation using newborn and adult rat experimental models of bile duct ligation, we demonstrated that although the initial responses of ductule proliferation and inflammatory infiltration were less intense in newborn animals, portal and periportal fibrosis were more extensive in newborns compared to adult animals.\textsuperscript{19} In the present study, we utilized the same experimental model and immunohistochemical staining techniques to detect desmin and smooth muscle alpha-actin (-SMA), which are classic markers of myofibroblastic cells.\textsuperscript{19,20} Our aim was to determine if the stellate (perisinusoidal) cells and the myofibroblasts of the newborn animals respond in a different manner compared to those of adult animals during biliary obstruction. These findings will enhance the understanding of the pathophysiology of biliary-type portal fibrosis of cholestatic diseases of childhood, including biliary atresia.

**METHODS**

The study was approved by the Ethical Committee for Research Project Analysis of our institution, and was carried out according to the international guidelines regarding the use of laboratory animals.

**Surgical operations**

The experimental model of cholestasis was created through common bile duct ligation (BDL) and sectioning between ligations, as previously described.\textsuperscript{19-25} Male and female Wistar rats were used in the experiments. The animals were divided into two groups: young six-day old rats weighing between 8 to 13.9 g (mean weight of 11.4 g ± 0.038) submitted to common BDL (n=90), and adult rats weighing between 199.7 and 357 g (mean of 257.9 g ± 1.58) submitted to common BDL (n=90). The control group consisted of 10 adult and 10 six-day old rats that were submitted to the same anesthetic procedures and liver biopsy sampling without the common bile duct ligation procedure. The young and adult animals that were submitted to surgery were randomly divided and killed on the 3\textsuperscript{rd}, 5\textsuperscript{th}, 7\textsuperscript{th}, 14\textsuperscript{th}, 21\textsuperscript{st} or 28\textsuperscript{th} day post-BDL. Wedge biopsies of the left liver lobe were collected from the young and adult animals submitted to BDL, as well as the control animals. The fragments were kept in a buffer solution with 10% formaldehyde for a period of 24 to 48 hrs, after which they were paraffin-embedded. Sections 3 μm in thickness were cut from the paraffin blocks.

**Immunohistochemical studies**

**Desmin:** Immunohistochemical staining for desmin was performed using the mouse anti-human desmin antibody (DAKO® Corporation A/S Denmark, clone D33) at a 1/200 concentration. Antigenic recovery of the material was performed by boiling the sections at 95°C in a citrate buffer at pH 6. The secondary kit used to detect immunohistochemical staining was the Vectastain® ABC kit (Vector® laboratories). The chromogen used was 3,3-diamino benzidine (Sigma®, code D-8001), and counterstaining was performed with Harris hematoxylin. Immunohistochemistry was used to identify the populations of myofibroblast and stellate cells to investigate their location in the normal liver of young and adult rats, to assess the degree of desmin expression, and to perform a semi-quantitative analysis of desmin expression throughout the observation period after ligation in animals of different ages. The semi-quantitative evaluation was performed by the global analysis of the entire lamina by two experimental pathologists in a double-blind analysis in order to estimate the number of desmin-positive cells in the different areas under study: the liver lobule, the portal region and the interface zone. The semi-quantitative measurements were performed using scores from 0 to 4, with 0 indicating the absence of positive staining, 1 indicating the presence of mild staining (+); 2 indicating the presence of moderate staining (++); 3 indicating the presence of intense staining (+++) and 4 indicating the presence of very intense staining (++++)

**Smooth muscle alpha-actin (-SMA):** Immunohistochemical staining for smooth muscle alpha-
actin (α-SMA) was performed using a mouse anti-human alpha-actin antibody, diluted 1/500 (DAKO® Corporation A/S Denmark, clone 1A4). Antigenic recovery of the material was performed by boiling the sections at 95º C in a citrate buffer at pH 6. The secondary kit utilized was the Vectastain® ABC kit (Vector® laboratories). The chromogen used was 3,3-diamino benzidine (Sigma®, code D-8001), and counterstaining was performed with Harris hematoxylin. Immunohistochemistry was used to identify the activated stellate cells in the liver lobule and myofibroblast populations in the portal space and interface area, to evaluate the degree of α-SMA expression, and to perform a semi-quantitative analysis of α-SMA expression throughout the observation period after ligation in animals of different ages, using the same criteria described for the evaluation of desmin expression.

Statistical Analysis

The histological data were recorded in a double-blind analysis by two pathologists, as previously described, and were compared at each phase of the experiment between adult and young animals. Statistical analysis was performed with the non-parametric Mann-Whitney Rank Sum Test, using Sigmastat® software. The null hypothesis that the samples were equal was rejected for a $p$ value < 0.05.

RESULTS

Desmin

Normal livers from animals of different ages showed desmin expression in the smooth muscle cells of blood vessel walls, in a few myofibroblasts of the portal stroma, and in certain cells located in zones 1 and 3 of the liver lobules. These cells were identified as stellate cells (perisinusoidal or Ito cells) due to their location and characteristic star-shaped morphology with cytoplasmic extensions. The sham-operated animals showed exactly the same expression of normal livers in both age groups.

After BDL, the desmin expression increased significantly in young as well as in adult animals when compared to the control group. This increase was observed mainly inside the liver lobules, where the population of stellate cells increased significantly in both groups of animals.

On the 5th day after operation, desmin expression increased to a similar extent in both groups. However, from the 7th day onwards, higher levels of desmin expression were observed in the young animals, reaching a maximum value on the 14th day after the operation. In contrast, desmin expression in the adult animals reached its maximum value only on the 28th day. In addition, desmin expression in myofibroblasts located in the interface zone between the portal space and the lobule reached higher levels in a shorter period of time in the young animals when compared to the adult animals. However, the portal myofibroblasts showed a very weak and constant staining intensity throughout the observation period after BDL. The expression of desmin in the portal myofibroblasts was higher in the young animals (Figure 1).

Smooth muscle alpha-actin (α-SMA)

α-SMA was expressed in the intermediary layer of portal tract vessels and in some cells around the terminal liver venules in the normal liver. Occasionally, α-SMA-positive cells were found in the fibrous stroma of biliary ducts and liver sinusoids. The sham-operated animals showed exactly the same expression of normal livers in both age groups. Three days after BDL, myofibroblasts that stained intensely...
for α-SMA could be easily identified, and they formed layers around the proliferated bile ductules. In both groups of rats, the population of α-SMA-positive cells continued to increase throughout the post-operative period up until the 7th day, and maintained the same expression level thereafter until the end of the experiment. The expression of α-SMA in the portal myofibroblast population was very different from that observed for desmin expression, indicating a different pattern of marker expression in this cell population, i.e., while the myofibroblasts located in the lobule and in the interface express desmin, those located in the portal space express α-SMA at high levels.

The expression of α-SMA by the stellate cells began to appear on the 5th day post-CBDL, and the same pattern of expression was maintained up until the 14th day in both young and adult animals. From the 21st day onwards, -SMA expression increased, reaching maximum levels on the 28th day in the adult rats compared to its expression in the young rats. A constant finding in all the animals on the 5th day post-BDL was the presence of stellate cells with -SMA expression distributed along zone 1 of the lobule, the most distal zone of the centrilobular vein (zone 3), thus “bridges” of myofibroblast cells joining the portal spaces were present. With time, the stellate cells subsequently occupied all zones of the liver lobule.

Myofibroblasts located in the interface between the portal space and the lobule also expressed -SMA, with similar increases in the expression levels in animals of different ages. The interface myofibroblasts showed higher expression of α-SMA than desmin at the end of the observation period (Figure 2).

In summary, desmin expression in the myofibroblast cells post-BDL was higher in the young rats, reaching its peak value in a shorter time compared to the adult animals. This observation indicates there is an actual increase in the number of collagen-producing myofibroblast cells in young animals, which suggests that more extensive fibrosis is occurring in the younger rats. α-SMA expression translates into the activation of the stellate cells. The differences in α-SMA expression between the groups were smaller, and in certain situations, the α-SMA expression, especially in stellate cells, was higher in adult animals.

**DISCUSSION**

The main population of cells involved in extracellular matrix protein synthesis, mesenchymal myofibroblast cells, was studied by immunohistochemical analysis. Of the sub-populations of these cells, stellate cells have been the focus of several studies as they are the major source of collagen production. However, in an experimental model of common bile duct ligation (BDL), other myofibroblast cell populations can also be involved with the initial stages of fibrogenesis, especially the portal myofibroblasts and myofibroblasts located in the interface zone, between the portal space and the lobule. In this experimental model, as well as in several clinical forms of cholestatic diseases, the type of fibrosis that occurs is known as biliary-type portal fibrosis.

In this study, the “sectorial” expression of desmin and smooth cell alpha-actin by stellate cells, portal myofibroblasts and interface myofibroblasts were evaluated in a semi-quantitative analysis. The results obtained showed that there was discordance in the expression of markers in different myofibroblast populations. In particular, the myofibroblasts located in the portal space showed weak desmin expression and strong α-SMA expression. These observations indicate that there is a different pattern of marker expression in this cell population. In a previous study of liver injury caused by carbon tetrachloride and

![Figure 2 - Bar chart showing the expression of α-SMA at each phase of the experiment in young rats (YR) and adult rats (AR). The values expressed are medians](image-url)
BDL in adult rats, the authors studied the populations of myofibroblasts in the liver, and obtained similar results regarding the expression of desmin and α-SMA in the portal cells. In our investigation, the expression of desmin after BDL was higher in the young rats, with all myofibroblast populations reaching the peak desmin expression more quickly than the adult animals. This detail indicates that there is an actual increase in the number of myofibroblast cells in young animals, which suggests that a more extensive fibrosis process is occurring.

The differences in α-SMA expression between the age groups were not so apparent. In some instances, the expression of α-SMA was higher in adult animals, especially in stellate cells (28th day). A possible explanation for this observation could be the fact that in this model of biliary-type portal fibrosis, the most important cells in the initial stages of fibrogenesis are the portal and interface myofibroblasts, and not the stellate cells located in the liver lobule. There were no statistical differences in the activation (α-SMA expression) of the interface myofibroblasts in animals of different ages.

In conclusion, this study demonstrates that in young rats with BDL, the population of collagen-producing cells increased to a greater extent compared to adult animals. This finding may explain why young animals with bile duct obstruction experience a more intense portal fibrosis that is similar to the pathology observed in the livers of newborns with biliary-type portal fibrosis, such as biliary atresia.
