Abstract

We report the in-orbit performance of the Gas Slit Camera (GSC) on the MAXI (Monitor of All-sky X-ray Image) mission carried on the International Space Station (ISS). Its commissioning operation started on August 8, 2009, confirmed the basic performances of the effective area in the energy band of 2–30 keV, the spatial resolution of the slit-and-slat collimator and detector with 1.5° FWHM, the source visibility of 40–150 seconds for each scan cycle, and the sky coverage of 85% per 92-minute orbital period and 95% per day. The gas gains and read-out amplifier gains have been stable within 1%. The background rate is consistent with the past X-ray experiments operated at the similar low-earth orbit if its relation with the geomagnetic cutoff rigidity is extrapolated to the high latitude. We also present the status of the in-orbit operation and the calibration of the effective area and the energy response matrix using Crab-nebula data.

Key words: instrumentation: detectors – X-rays: general – X-rays: individual (Crab Nebula)

1. Introduction

MAXI (Monitor of All-sky X-ray Image) is the first astronomical mission operated on the ISS (International Space Station) (Matsuoka et al. 2009). The payload was delivered to the ISS by Space Shuttle Endeavour on July 16, 2009, and installed on the Japanese Experiment Module – Exposed Facility (JEM-EF or Kibo-EF) on July 24. The mission was designed to achieve the best sensitivity and the highest energy resolution among the all-sky X-ray monitors performed so far by using two kinds of X-ray slit cameras, Gas Slit Camera (GSC, Mihara et al. 2011) and Solid-state Slit Camera (SSC, Tomida et al. 2011), which work complementarily.

The GSC is the main X-ray camera to cover the energy band from 2 to 30 keV with a large area. It employs conventional slit camera that consists of Xe-gas proportional counters and slit-and-slat collimators. Twelve gas counters achieve a large detector area of 5350 cm². They are assembled into six identical units to cover wide fields of views (FOVs) of 1.5 × 100 degree². They are embodied in the MAXI payload module such that they cover the earth-horizon and the zenith directions with an equal area. It enables us to cover the entire sky every 92-minute orbital period even if the GSC has to be partly downed in a heavy particle-radiation environment such as the passage of the SAA (South Atlantic Anomaly). The Xe-gas counters employ resistive carbon-wire anodes to acquire one-dimensional position sensitivity. The gas volume of each counter is separated into six carbon-anode cells for main X-ray detectors and ten tungsten-anode cells for veto counters. The veto cells surround the carbon-anode cells to reduce backgrounds by the anti-coincidence-hit logic. Total 14 anode signals in each counter are read out independently through an electronics unit and processed by on-board data processors. Figure 1 illustrates the schematic views of a single GSC camera unit and FOVs of the whole six units on the ISS low-earth orbit. The details of the instruments are described in Mihara et al. (2011). This paper presents the GSC in-orbit performance including the operation and calibration status. The SSC in-orbit performance is presented in Tsunemi et al. (2010).

2. Operation

2.1. Initial Operation

The main power of the MAXI payload is supplied from the JEM-EF via the Payload Interface Unit (PIU). It was activated on August 3, one week later since the payload was installed on the JEM-EF. On August 4, the GSC electronics units (GSC-E) including the Radiation-Belt Monitor (RBM) were switched on. The on-board RBM parameters, thresholds of the lower discriminators and count-rate criteria to down the gas counters, were then
set up using the data taken for the first three days. On August 8, the high voltage of the first gas counter was activated and increased up to the nominal operation voltage of 1650 V. The first test observation was then performed for three hours and various analog/digital-electronic functions were verified. All the 12 counters were activated at the nominal 1650 V since August 10 to 13 one by one.

Each gas counter has 14 anode signals for both two ends of six carbon-wire anodes and two veto signals. Each anode signal has individual pre-amplifier, a shaping amplifier, a lower discriminator (LD), and an Analog-to-Digital Converter (ADC) which produces 14-bit pulse height. The gain of the shaping amplifier and the threshold of the lower discriminator of each signal can be changed by command. These parameters are adjusted according to the gas gain of individual anode wire. The first all-sky image by all 12 counters was taken on August 15.

2.2. RBM

GSC incorporates Radiation-Belt Monitor (RBM) to monitor the flux of the cosmic rays in orbit. Two silicon-PIN-diode detectors with 0.2-mm thickness and 5×5 mm² area are equipped with each of GSC horizon and zenith center units. The detector on the horizon unit (RBM-H) is faced to the tangential direction of the ISS motion along the earth horizon. The zenith unit (RBM-Z) is faced perpendicular to the horizontal plane. The RBMs always monitor count rates of cosmic rays with a certain energy deposit, whose threshold can be changed by commands. The level of the threshold is set at 50 keV, which corresponds to the half of the minimum ionization-loss energy of the relativistic particles.

Figure 2 shows the RBM count-rate maps on the ISS orbital area by RBM-H and RBM-Z units, respectively, averaged over the data taken for the first year. The ratio of the RBM-H to the RBM-Z count rate is shown at the bottom where contours of inclination angle of the magnetic field from the earth-horizontal plane are overlaid. The two RBM rates agree with each other in the low count-rate area below 0.2 Hz, where the anti-correlations with the geomagnetic cutoff rigidity (COR) are clearly seen. It indicates that the origins are energetic cosmic rays. The cosmic-ray flux ∼ 1 counts cm⁻² s⁻¹ and its relation with the COR are consistent with those obtained by ASCA (Makishima et al. 1996) and Suzaku (Kokubun et al. 2007) in low-earth orbit although the altitude of the ISS, 340–360 km, is different from that of these satellite, 530–590 km.

While the two RBM rates are agreed at the low radiation area, they are quite different in the high radiation area around the SAA and the both geomagnetic poles located at the north of the north American continent and the south of the Australian continent. The RBM-H rate is higher by an order of magnitude than the RBM-Z rate in these area. From the correlation between their ratio and the inclination of the magnetic field, the difference is considered to be due to the anisotropy of the flux of trapped particles. A large number of cosmic-ray particles trapped by the geomagnetic fields are moving circularly on the horizontal plane around the magnetic pole. The RBM-Z detector faced on the zenith direction is insensitive to the particles moving on the horizontal plane. The anisotropy of the trapped particles at the high latitude has also been recognized by images of particle tracks taken by the SSC CCD imager (Tsunemi et al. 2010).
2.3. High Voltage Operation

We started full GSC operation with twelve counter units, GSC0, ..., GSC9, GSCA, GSCB, on August 15, 2009. The high voltages of all the twelve gas counters were set at the nominal 1650 V. They are reduced to 0 V when the ISS passes through heavy particle background area defined by an on-board Radiation-Zone (RZ) map. In the beginning of the mission, we set the RZ map only at the SAA.

On September 8, 2009, the analog power on the GSC6 counter was suddenly down. It was followed by the power down of another counter, GSC9, on September 14. The data indicate that a carbon-anode wire in each of these counters was fractured. It was also suggested that the location fractured on the carbon wire would be where a large amount of discharges occurred repeatedly.

We then changed the counter operation strategy so that any risks to cause potential damages on the carbon-anode wire such as discharge and heavy irradiation should be avoided as much as possible. The high-voltage reduction at the high latitude above 40° was employed since September 23. Two noisy counters, GSCA and GSCB, which are considered to be fractured sooner, were also tentatively stopped on September 26.

On March 26, 2010, the analog power on the GSC3 counter was downed, which were considered to be due to a carbon-wire fracture by breakdown discharge again. Since then, the operation voltage was reduced to 1550 V if the counter had any discharge experience.

As the results of these limited HV operation, the effective observation efficiency is reduced to about 40%. It is expected to reduce the sensitivity. The three counters suffering from the breakdown will be soon activated with great care.

3. In-Orbit Performance

3.1. Background

The GSC counter has a one-dimensional position sensitivity and performs scanning observation. Backgrounds for any X-ray sources on the sky can be roughly estimated from the levels of the adjacent source-free region. The studies of the backgrounds are important because the residual backgrounds and its uncertainties limit the source-detection sensitivity.

3.1.1. LD-hit Rate and Processed Event Rate

Each GSC gas counter embodies six carbon-anode cells for main X-ray detector and the veto cells surrounding the carbon-anode cells. The cosmic-ray backgrounds are screened out on board by applying an anti-coincidence matrix to hit patterns of all anode signals in each counter. The efficiency of the background reduction depends on the LD threshold of the read-out signals. The amplifier gains and LD levels of all the read-out signals are tuned during the initial verification operation.

The background rates of all the 12 GSC counters are found to have a similar time variation during the entire observation-operation period. They exhibit clear anti-
correlations with the geomagnetic COR in orbit. Figure 3 illustrates the LD-hit rate, the processed event rate after the anti-coincidence cut, and the cleaned event rate with the PHA (Pulse-Height Amplitude) range of the 2-30 keV energy band against the COR. Each data point represents the rate per anode averaged over six anodes in a counter, GSC, every minute, taken for a day on August 18, 2009, except while the ISS is in a heavy particle-irradiation area detected by RBM and RZ map. Data expected to include significant X-ray events from celestial bright X-ray sources are also excluded. The ratio of the anti-coincidence-event rate to the LD-hit rate is about 1:30 and almost constant over the entire period. It is quite similar with the Ginga-LAC case (Turner et al. 1989). The LD-hit rate is well agreed with the RBM rate taking the detector area, 90 cm² per anode, into account. It indicates that they are the energetic cosmic-ray origin.

3.1.2. Energy Spectrum

Figure 4 shows energy spectra of the residual backgrounds sorted by COR and the estimated contribution of the unresolved Cosmic X-ray Background (CXB) within the FOV (e.g. Gendreau et al. 1995). The profile shows the fluorescent lines of Ti-K at 4.6 keV from the gas-counter body and Cu-K at 8.1 keV from the slat collimator made of phosphor bronze. These emission lines are used for the energy response calibration. The shape of the continuum in the energy band above 8 keV is quite sensitive to the COR. It suggests that the origins of these components would be energetic cosmic rays. The CXB component is expected to be dominant in the energy band below 5 keV at COR>8.

Figure 5 illustrates the background spectrum normalized by effective area, and those of the Ginga LAC (Hayashida et al. 1989) and the RXTE PCA (Jahoda et al. 2006), where expected contribution of the CXB in each instrument are included. Crab-like source spectra are shown together as the comparison. The GSC background is approximately 20 mCrab at 4 keV and 10 mCrab at 10 keV. The level is almost comparable to that of the Ginga LAC and slightly higher than that of the RXTE PCA.

3.1.3. Spatial Distribution

Figure 6 shows spatial distributions of the residual backgrounds along the anode wire in 2-10 and 10-30 keV energy bands and the estimated contributions of the CXB. Each GSC counter has a sensitivity gap at the center of the an-
The energy resolution of 18% at 5.9 keV was stable since the ground calibration tests. The results show that the gas gain is stable within 2%, which agrees well with the results of the vacuum-environment test on the ground. This information is employed for a PHA-to-PI (Pulse-height Invariant) conversion in the data reduction process.

3.2. Energy Response and Gain Stability

Each gas counter is equipped with a calibration source embodying radioactive isotope $^{55}$Fe at the end of one of six carbon anodes (the left-side end of carbon anode #2). It always exposes collimated X-ray beam with a diameter of 0.2 mm. The counter gas gain and energy resolution have been continuously monitored with the 5.9-keV line since the ground calibration test. The results show that the gas gain is stable within 2%, which agrees well with the results of the vacuum-environment test on the ground. The variation in orbit during the first year was within 0.8%. The energy resolution of 18% at 5.9 keV was stable within the statistical uncertainty.

The energy scale of the PHA of all the read-out signals are monitored at the entire location along the carbon-anode wire using Ti-K and Cu-K fluorescent lines in the background, as seen in figure 4. The time variations for the first year was within 1% in the entire counter area. This information is employed for a PHA-to-PI (Pulse-height Invariant) conversion in the data reduction process.

3.3. Detector Position Response and Stability

The incident X-ray position along a carbon-anode wire is calculated from the PHA ratio of two read-out signals to the both anode ends. All the required calibration data to derive the detector position from the PHA ratio were collected in the ground tests (Mihara et al. 2011).

The stability of the detector position response has been monitored with the calibration source since the ground calibration tests. The time variation of the calculated position during the first year was less than 0.2 mm that corresponds to an angular distance of 0.07° on the sky. It is small enough for the position determination accuracy of 0.2° achieved. The detector position resolution of 2.0 mm (FWHM) for 5.9-keV X-ray at the nominal anode voltage of 1.650 was constant within the statistical uncertainty of 0.05 mm (1 σ) since the ground tests.

3.4. Point Spread Function in the Anode-wire Direction

The point spread function (PSF) of the GSC is determined by the angular response of the slit-and-slat collimator and the position response of the position-sensitive gas counter along the anode wire. The collimator is designed to have an angular resolution of 1.0–1.5° in FWHM, which slightly depends on the X-ray incident angle. The position resolution of the gas counter depends on the X-ray energy. The resolution for X-rays with a normal incident angle is inversely proportional to the number of multiplied signal charges and varies from 4 to 1 mm in the GSC energy band from 2 to 30 keV (Mihara et al. 2011). For events with slant incident angles, the variation of the photon-absorbed depth in a gas cell can also degrade the position resolution. The relation between the positional scale on the detector and angular distance on the sky also depends on the incident angle. Thus, the PSF is represented by a complex function of X-ray energy and incident angle.

Figure 7 illustrates the cross-section profiles of PSF models for the direction along the detector anode-wire at each photon-incident angle, $\phi$, of 5° and 33° in 2–10 keV (soft) and 10–30 keV (hard) energy bands (see the geometry in Figure 1). We also show the actual observed profiles taken from the data of a bright X-ray source, Sco X-1, for comparison. The PSF models agree with the data within the statistical uncertainty. For events of $\phi = 5^\circ$, which is close to the normal incident angle, the angular resolution in the hard band is better than that in the soft band according to the better detector position resolution along the anode wire for the higher-energy X-rays. For events with a slant incident angle of $\phi = 33^\circ$, the variation of the absorbed depth yields the broad distribution along the anode wire and degrades the resolution especially in the...
effective areas during scan transits at typical two source-acquisition angles of $5^\circ$ and $72^\circ$, where the angular scales of the collimator transmission function are also indicated at the top on each panel. The observed count rates of Sco X-1 taken at the same acquisition angle are plotted together for comparison. The calculated scan duration and the observed period are agreed well with each other.

3.6. Exposure Map and Sensitivity

An exposure map on the sky for a given period is calculated from the counter HV-operation history, the detector effective area as a function of a photon incident angle, and information of the ISS orbit, attitude, and configuration parameters interfering the FOV such as the solar paddles, the space-shuttle vehicle docked on the ISS. Figure 10 shows the actual exposure maps by all operated GSC counters for 92 minutes of an ISS-orbital cycle, one day, and 27 days since January 2, 2010, 00:00 (UT), calculated from all the required information during these periods. GSC covers approximately 85% of the whole sky for one orbit except for the orbits including the SAA passage, and 95% for a day. The daily map has uncovered area for the Sun direction, the solar-paddle shadow, and the rotation pole that drift on the sky according to the precession of the ISS orbit. We can achieve the 100% full coverage in every three weeks.

An actual exposure time for an arbitrary direction on the sky was typically 4000 cm$^2$s per day. It is about one third of the initial expectation because the HV operation at the high latitude above $40^\circ$ was stopped and four counters out of 12 were disabled in these period. The daily 5-$\sigma$ source sensitivity is expected to become 15 m Crab, which is three times worse than that of the pre-flight simulation (Matsuoka et al. 2009).

4. Calibration Status

We here present the status of the GSC response calibration for data taken at the nominal HV of 1650 V. We also exclude data detected by anodes #1 and #2 of all GSC counters because some of them show complicated energy-PHA relations at low PHA, which is probably due to feedback crosstalks on the circuit board. The responses functions for the data taken at the reduced HV of 1550 V and by the anode #1 and #2 are being developed and will be updated soon.

4.1. Alignment and Position Localization Accuracy

The attitude of the MAXI payload module is continuously measured with the on-board Attitude Determination System (ADS), which consists of a Visual Star Camera (VSC) and a Ring Laser Gyroscope (RLG). Its accuracy is estimated to be better than an arc minute from the ground calibration tests (Horike et al. 2009). The source location of an incident X-ray on the sky is calculated from the position coordinates on the detector where the X-ray is absorbed and the attitude parameters at the event time. The alignments of the collimators and detectors on the payload module are calibrated.

![Fig. 7. PSF cross-section profiles along the detector anode-wire direction at each source-incident angle, $\phi$, of 5$^\circ$ (top) and 33$^\circ$ (bottom) in two energy bands of 2–10 keV (solid line) and 10–30 keV (dashed line). The power-law energy spectrum of photon index, 2.1, is assumed. Actual observed profiles of Sco X-1 taken at each source angle are plotted with 1-$\sigma$ error bars in the 2–10 keV (circle) and 10–30 keV (triangle) bands.](image-url)

Fig. 9. Time variation of effective area during each scan transit at source-acquisition angle of $5^\circ$ for GSC_1 and GSC_2 units (top) and $72^\circ$ for GSC_2 units (bottom). The angular scale of each transit is shown at the top of each panel. Observed raw event rates of Sco X-1 by each GSC unit are plotted together with 1-sigma error bars.

Fig. 10. GSC exposure map by scans of 92-minute orbital period (top), 1 day (middle), and 27 days (bottom) since 2010 January 2 00:00 (UT). The color scales of all three panels are identical and represent the effective exposure for the sky direction in the units [cm$^2$ s]. The uncovered areas for the rotation pole, the Sun direction, the SAA, and the interference with the solar paddles are indicated with arrows.

using standard X-ray sources whose positions and intensities are well-known. The accuracy of $0.2^\circ$ in the 90% containment radius of the best determined position has been confirmed so far using several bright-source samples selected randomly (Morii et al. 2011).

4.2. Effective Area and Light curve

The visibility and the area of each GSC unit for a given X-ray source on the sky are always changing according to the ISS orbital motion and interferences with other relevant ISS activities, as shown in section 3.5. To derive the intrinsic time variation of a certain X-ray source, the time-dependent effective area for the target has to be known. The light-curve response builder calculates the area curve of each GSC unit from the source coordinates, the ISS location, attitude, and the area of the GSC unit as a function of the source incident angle. The area of all the GSC units were calibrated on the ground using pencil
X-ray beams (Morii et al. 2006).

The top panel of figure 11 shows the obtained light curve of Crab nebula in the 4–10 keV energy band since the mission start on August 15, 2009. The data are collected from the area-corrected photon count rates for each day. Backgrounds are estimated from the count rates for the adjacent sky region, which corresponds to the data obtained from the successive time periods. A power-law energy spectrum with a photon index, $\Gamma = 2.1$, is assumed in the effective-area correction. The light curve should be approximately constant and consistent with the flux of the standard Crab model. The measured average flux over the entire period, $1.25 \text{ photons cm}^{-2} \text{s}^{-1}$, agrees with the standard Crab value (Kirsch et al. 2005; Weisskopf et al. 2010). However, the fit to a linear model results in a reduced chi-squared $\chi^2_{\nu} = 1.74$ for 364 degrees of freedom (DOF), which is not accepted within the 90% confidence limit. It is due to the limit on the effective-area calibration accuracy on the daily basis. The error on the daily flux in the 4–10 keV band is estimated to be 3% with the 1-$\sigma$ range. The calibration over the entire 2–30 keV energy range is in progress.

Recently, Wilson-Hodge et al. (2011) presented evidences of flux variations of Crab nebula by $\sim$7% on a 3-year timescale, consistently observed by Fermi/GBM, RXTE/PCA, Swift/BAT, and INTEGRAL/ISGRI. The flux in 2–15 keV band observed by RXTE/PCA exhibits a 5.1% decline from MJD 54690 to 55435. We examined the variation with the GSC data. The bottom panel of figure 11 shows the variation of the obtained GSC 4–10 keV flux by each interval of about 100 days. The start and the end of each interval are slightly adjusted according to the observation-time coverage. A continuous decline is seen clearly. The fluxes averaged by the long term are derived from large event data taken by various camera angles and detector positions. Therefore, the calibration uncertainty of the effective area on daily basis, 3% in 1 $\sigma$, is supposed to be smeared out in it and the observed decline is considered to be real.

We fitted the data to a linear function and obtained the decline ratio of $2.2 \pm 0.5\%$ (1-$\sigma$ statistical uncertainty) from MJD 55058 to 55558. The ratio is slightly smaller than that extrapolated from the 5.1% decline from MJD 54690–55435 observed by RXTE/PCA in 2–15 keV band. We tried to fit the GSC data to a linear model with the fixed slope determined by the RXTE/PCA, as shown in figure 11. The fit is marginally unacceptable with $\chi^2_5 = 1.92$ for 5 DOF. It might imply the dependence of the variation amplitude on the energy band, as reported in Wilson-Hodge et al. (2011).

4.3. Energy Response Matrix

The energy response matrix is represented by a product of the effective area and the dispersion relation between the incident X-ray energy and the PHA of the output signal. The dispersion relation as well as the gas gain depend on the 3-dimensional location where the X-ray photon is absorbed in a detector gas cell. The spatial gain variation and the time variation in orbit are corrected event by event in the first data-reduction process using calibration data collected from the ground and in-orbit test results. All the dispersion relations required to derive the response matrix were taken in the ground test (Mihara et al. 2002).

The energy response builder calculates the effective area and the energy redistribution matrix for a target source at given sky coordinates during a given observation period. The program accumulates instantaneous response functions for the source location according to the variation of the incident angle during the active observation period.

Figure 12 shows a Crab spectrum by GSC taken for a day on August 15, 2009 (UT) and the best-fit power-law model with an interstellar absorption, folded by the response matrix obtained by the response builder. Backgrounds are extracted from events in the adjacent sky region. The best-fit parameters are summarized in table 1. The model-to-data ratio shows that the obtained spectrum is well reproduced within 10% over the 2-30 keV energy range. The best-fit absorption column density, $0.72 \pm 0.22 \times 10^{22} \text{ cm}^{-2}$ is slightly higher than the standard Crab value, $0.35 \times 10^{22} \text{ cm}^{-2}$ (Kirsch et al. 2005) although the fit with the absorption fixed at the standard value is also accepted within the 90% confidence limit. The discrepancy is considered to be in inaccuracy of the effective-area calibration at the low energy band. The fine calibration is in progress.
Table 1. Best-fit parameters for GSC Crab-nebula spectrum

| Model                      | \( N_H^a \)   | \( \Gamma^b \) | \( \text{Norm.}^c \) | \( \chi^2 \) (DOF) |
|----------------------------|---------------|---------------|-------------------|-------------------|
| Power-law, \( N_H \): free | 0.72 \( \pm \) 0.22 | 2.15 \( \pm \) 0.05 | 11.4 \( \pm \) 1.0 | 1.08 (43)         |
| Power-law, \( N_H \): fixed | 0.35          | 2.08 \( \pm \) 0.03 | 9.9 \( \pm \) 0.4  | 1.25 (44)         |

All errors represent 90% confidence limits of statistical uncertainty.

![Fig. 12. GSC Crab-nebula spectrum taken for a day on August 15, 2009 (UT) and the best-fit power-law model with a fixed absorption of 0.35 \( \times \) \( 10^{22} \) cm\(^2\) (top). Data-to-model ratio (bottom).](image1)

4.4. Timing

In-orbit timing calibrations are performed using signals from X-ray pulsars or binaries, such as Crab pulsar and Cen X-3 with 33 millisecond and 4.8 second period, respectively. Events within the PSF of these pulsars are extracted and applied to the barycentric correction. The pulsation of Crab pulsar can be detected for every one-day interval. Figure 13 show the folded pulse profiles since January 1 to January 5, 2010. The absolute timing and the relative stability are estimated by the relative pulse phase of the Crab pulsar to those with the radio wavelength (Lyne et al. 1993) and RXTE/PCA (Rots et al. 2004), and comparison of the Cen X-3 pulse period and phase with those of the Fermi/GBM (Meegan et al. 2009). We confirmed the timing stability of an order of \( 10^{-9} \).

5. All-sky image

Figure 14 shows the GSC all-sky X-ray image taken for the first year. The red, green, and blue color scales represent the intensity in 2-4, 4-8, and 8-20 keV energy band, respectively. The diameter of point source images roughly represents the relative brightness according to the PSF spread. We can easily see more than a hundred of discrete X-ray sources over the whole sky as well as unresolved Galactic ridge emission along the Galactic plane with a scale height of 1-2°.

6. Summary

The GSC in-orbit performance on the MAXI mission payload is verified from the initial commissioning operation. Table 2 briefly reviews the relevant parameters. They are summarized by the following points.

1. The optimal configurations of the read-out electronics and on-board data processing at the nominal high voltage of 1650 V are established. The gas gain and the amplifier gain are confirmed to agree with those expected from the ground calibration tests. The gain change during the first year is confirmed to be less than 1 %, which is small enough for the requirements of the calibration accuracy.

2. Two gas counters out of the twelve were turned off for the high-voltage breakdown during the first two-months commissioning operation and another breakdown occurred in the ninth month. These breakdown would be presumably caused by repeated discharges. The HV operation under the high particle-background, which includes area at the high latitude above 40° as well as the SAA, were stopped since September 27, 2009 in order to avoid any dam-
age that can develop into the discharges. The three counters suffering from the breakdown are now operated with a limited sensitivity using alive-anode partitions.

3. The background cosmic-ray rate is consistent with that extrapolated from the past experiments in the low-earth orbit using the relation with the geomagnetic COR. The efficiency of the on-board background rejection by the anti-coincidence-hit logic is also found to be comparable to those of the similar instruments, Ginga-LAC.

4. The PSF with an FWHM of 1.5°, the scan transit time from 40 to 150 seconds per orbital cycle, the all-sky coverages of 85% per 92-minute orbital period and 95% per day are verified, which agrees with the pre-flight design. The effective exposure time for a celestial target is typically 4000 cm² s. The daily 5-σ source sensitivity is expected to be 15 mCrab in the condition.

5. The instrument response in orbit has been calibrated using Crab nebula data. The fitting results verified that the uncertainty of the effective area and the energy response would be less than 10% if data of a few anodes suffering from cross talk on the circuit board are ignored. The relative timing accuracy was also confirmed to be normal.

We are grateful to Mark Finger and Fermi/GBM pulsar project team for providing the pulsar ephemeris data for timing calibration. We also thank Keith Jahoda for stimulating and constructive comments. This research was partially supported by the Ministry of Education, Culture, Sports, Science and Technology (MEXT), Grant-in-Aid for Science Research 19047001, 20244015, 21340043, 21740140, 22740120 and Global-COE from MEXT “Nanoscience and Quantum Physics” and “The Next Generation of Physics, Spun from Universality and Emergence”.

Fig. 14. GSC all-sky image taken for the first year. Red, green, and blue color maps are scaled logarithmically and represent the intensities in 2-4, 4-8, and 8-20 keV bands, respectively.
Table 2. Summary of GSC in-orbit performance

| Parameter                      | Value                                      |
|-------------------------------|--------------------------------------------|
| Spatial resolution            | $1.5^\circ$ (FWHM)                         |
| Source localization accuracy  | $0.2^\circ$ (90% containment radius)       |
| All-sky coverage              | 85% per orbit (nominal 92 minutes), 95% per day |
| Exposure                      | 4000 cm$^2$ s per day (typical)            |
| Energy resolution             | 18% ($1\sigma$) at 5.9 keV                |
| Effective area accuracy       | 3% ($1\sigma$) at 4–10 keV                |
| Sensitivity                   | 15 mCrab per day in 2–30 keV (typical)     |
