Linear Systematics Mitigation in Galaxy Clustering in the Dark Energy Survey Year 1 Data

Erika L. Wagoner, Eduardo Rozo, Xiao Fang, Martín Crocce, Jack Elvin-Poole, and Noah Weaverdyck

(DES Collaboration)

ABSTRACT

We implement a linear model for mitigating the effect of observing conditions and other sources of contamination in galaxy clustering analyses. Our treatment improves upon the fiducial systematics treatment of the Dark Energy Survey (DES) Year 1 (Y1) cosmology analysis in four crucial ways. Specifically, our treatment 1) does not require decisions as to which observable systematics are significant and which are not, allowing for the possibility of multiple maps adding coherently to give rise to significant bias even if no single map leads to a significant bias by itself; 2) characterizes both the statistical and systematic uncertainty in our mitigation procedure, allowing us to propagate said uncertainties into the reported cosmological constraints; 3) explicitly exploits the full spatial structure of the galaxy density field to differentiate between cosmology-sourced and systematics-sourced fluctuations within the galaxy density field; 4) is fully automated, and can therefore be trivially applied to any data set. The updated correlation function for the DES Y1 redMaGiC catalog minimally impacts the cosmological posteriors from that analysis. Encouragingly, our analysis does improve the goodness of fit statistic of the DES Y1 3×2pt data set (Δχ² = −6.5 with no additional parameters). This improvement is due in nearly equal parts to both the change in the correlation function and the added statistical and systematic uncertainties associated with our method. We expect the difference in mitigation techniques to become more important in future work as the size of cosmological data sets grows.

Key words: methods: data analysis – cosmology: observations – galaxies: photometry – dark energy – methods: statistical

1 INTRODUCTION

Galaxies are an important tool for studying the distribution of matter in the Universe and testing cosmological models. The correlation between the shapes of galaxies can be used to measure the weak gravitational lensing field, which is a direct measure of the total mass along lines of sight (see, e.g., Brainerd et al. 1996; Mellier 1999; Refregier 2003; Yoo & Seljak 2012; Weinberg et al. 2013). Because galaxies are a biased tracer of the mass, their clustering also carries within it cosmological information (e.g., Beutler et al. 2011; Alam et al. 2017; Bautista et al. 2018; Abbott et al. 2019; Nishimichi et al. 2020; Icaza-Lizaola et al. 2020; Colas et al. 2020). In addition, the tangential distortion of background galaxies around the position of foreground galaxies—usually referred to as galaxy–galaxy lensing—can be used to study the correlation between the foreground galaxies and the matter around them (e.g., Brainerd et al. 1996; Fischer et al. 2000; Sheldon et al. 2004; Mandelbaum et al. 2006; Yoo & Seljak 2012; Weinberg et al. 2013). The combination of all three measurements, sometimes referred to as “3×2pt” for the use of three 2-point functions, can break the degener-
acy between the galaxy bias and the clustering amplitude of matter (see, e.g., Bernstein & Jain 2004; Hu & Jain 2004; Bernstein 2009; Weinberg et al. 2013; Krause & Eifler 2017, and references therein). These 3x2pt analyses are the focus of ongoing surveys such as the Kilo Degree Survey (KiDS; Hildebrandt et al. 2017), the Dark Energy Survey (DES; The Dark Energy Survey Collaboration 2005; Dark Energy Survey Collaboration 2016), and the Hyper Suprime-Camera Survey (HSC; Aihara et al. 2018). Many other analyses have also applied a similar combined-probes approach to a variety of data sets (see, e.g., Mandelbaum et al. 2013; More et al. 2015; van Uitert et al. 2018; Joudaki et al. 2018; Abbott et al. 2018). These types of combined analyses can also help to mitigate systematics that impact only one of the three 2-point measurements. The clustering of galaxies can also be used without weak lensing to observe the signature of Baryon Acoustic Oscillations (BAO), which can be used to measure the cosmic expansion history (e.g., Alam et al. 2016; Rezaie et al. 2017; Bautista et al. 2018; Abbott et al. 2019; Icaza-Lizaola et al. 2020).

Wide field stage II dark energy experiments (such as the Sloan Digital Sky Survey [SDSS; York et al. 2000], the WiggleZ Dark Energy Survey (Drinkwater et al. 2010) and the Canada-France-Hawaii Telescope Legacy Survey [CFHTLS; Cuillandre et al. 2012] and stage III dark energy experiments (e.g., KiDS, DES, HSC, and eBOSS) have provided imaging and spectra for hundreds of millions of galaxies, and stage IV experiments such as the Dark Energy Spectroscopic Instrument (DESI; Levi et al. 2013), the Rubin Observatory’s Legacy Survey of Space and Time (LSST; Ivezić et al. 2019), the Nancy Grace Roman Space Telescope (Spergel et al. 2015), and Euclid (Laureijs et al. 2011) are expected to increase that number substantially. As the number of observed galaxies increases, the statistical uncertainty on measurements made with them decreases (Suchyta et al. 2016). Consequently, our understanding and treatment of the systematic effects that impact galaxy clustering measurements must be improved if the uncertainties on the inferred cosmological parameters from such galaxy surveys are to remain statistics-dominated. In Peebles (1973), the author points out that the variable effects of “galaxy obscuration and confusion” almost always cause the apparent density of galaxies to vary across the sky, and that coherent patterns of large angular scales “must be treated with caution unless one can make a reliable correction for it.”

There are a large number of potential contaminants that can result in this type of coherent fluctuations, e.g. star-galaxy separation, stellar occultation, extinction, and variations in observing conditions like airmass or sky brightness. Differentiating between the true cosmologically-sourced fluctuations and those caused by such survey properties has been the subject of many studies over the years (see, e.g., Rybicki & Press 1992; Tegmark 1997; Tegmark et al. 1998; Vogeley 1998; Hivon et al. 2002; Slosar et al. 2004; Ho et al. 2008; Ross et al. 2011, 2012; Ho et al. 2012; Bergé et al. 2013; Pullen & Hirata 2013; Leistedt et al. 2013; Leisted & Peiris 2014; Suchyta et al. 2016; Prakash et al. 2016; Ross et al. 2017; Delubac et al. 2017; Laurent et al. 2017; Raichoor et al. 2017; Elvin-Poole et al. 2018; Bautista et al. 2018; Alonso et al. 2019; Nicola et al. 2020; Rezaie et al. 2020; Weaverdyck & Huterer 2020). Rezaie et al. (2020) identify three broad categories of mitigation techniques: (a) Monte Carlo simulation of fake objects; (b) mode projection; and (c) regression.

The first of these methods, involving injecting artificial sources into real images, is extremely promising. It results in forward-modeling the survey selection mask imposed by real imaging properties. Examples of this method include Bergé et al. (2013) and Suchyta et al. (2016). However, this technique is computationally expensive, and therefore less utilized than the other methods.

Techniques utilizing mode projection typically involve down-weighting the spatial modes that are strongly correlated with survey properties by assigning a large variance to them. This technique is explained and utilized in, e.g., Rybicki & Press (1992); Tegmark (1997); Tegmark et al. (1998); Hivon et al. (2002); Slosar et al. (2004); Ho et al. (2008); Pullen & Hirata (2013); Leistedt et al. (2013); Leistedt & Peiris (2014); Elsner et al. (2017); Alonso et al. (2019); Nicola et al. (2020). The variance of the estimated clustering increases as more survey properties are considered unless a threshold is used to limit the number of survey property maps. However, using such a threshold has been shown to introduce a bias in the resulting two-point function (Elsner et al. 2016). Regression-based techniques attempt to model the impact of the survey properties on the galaxy density, fitting the parameters of the model by cross-correlating the galaxies and systematic fluctuations or by using a least-squares estimate (see, e.g., Ross et al. 2011, 2012; Ho et al. 2012; Prakash et al. 2016; Ross et al. 2017; Delubac et al. 2017; Laurent et al. 2017; Raichoor et al. 2017; Elvin-Poole et al. 2018; Bautista et al. 2018). For instance, Ross et al. (2011); Howlett et al. (2012) fit for the impact of observing conditions in the correlation function and power spectrum, respectively. The disadvantage with this method is that any spurious correlation between the 2-point function of the galaxies and the survey properties will result in a correction, even if the fluctuations are not spatially related. This makes it easy to over-correct for systematic fluctuations, which may bias the resulting correlation function estimate.

As part of the analysis of the DES Y1 “Gold” data release, Elvin-Poole et al. (2018); hereafter Paper I also fit for the impact of survey properties, but using one of the alternative suggestions from Ross et al. (2011) of applying the corrections one at a time in order to account for potential correlations between different sources of systematic fluctuations. Briefly, the method of Paper I is as follows: the average number of galaxies per pixel \( N_{\text{gal}} \) is measured for all pixels with a survey property value \( s \) within a bin \( \Delta s \in [s_{\text{min}}, s_{\text{max}}] \) for one of the survey property maps, relative to the average number of galaxies per pixel in all pixels \( N_{\text{gal}} \). A model is fit across all bins of the survey property values, and the \( \Delta N^2 \) for this model compared to a null test where \( N_{\text{gal}} / (N_{\text{gal}} - 1) \) is calculated. The significance of the survey property map is defined by comparing this \( \Delta N^2 \) to the sixty-eighth percentile of the equivalent quantity measured in 1000 contaminated Gaussian mock catalogs. This procedure is repeated for each survey property map and the maps are ranked by significance. A correction is applied for the most significant map to the measurements of \( N_{\text{gal}} / (N_{\text{gal}} - 1) \), and the significance of each map is re-calculated. To avoid over-correction, this iterative process continues until none of the survey property maps have a significance above some target threshold.
However, it is not necessarily the case that the effects of the various survey properties can be separated in this manner. For instance, this method precludes the possibility that significant systematic fluctuations can arise from the coherent contribution of multiple sources of systematics despite each individual survey property map being negligible by itself. Also, the analysis in Paper I included the spatial structure of the galaxy distribution only through the covariance in the galaxy densities binned by survey property. The analysis method introduced in this paper explicitly incorporates the density and spatial separations of neighboring pixels for determining the coefficients of the fluctuations sourced by survey properties: it is a much finer-grained look at that spatial structure.

Several other recent studies have attempted to use the regression-based technique directly with the galaxy density field while incorporating the spatial structure of the galaxy density field (see, e.g., Prakash et al. 2016; Delubac et al. 2017). However, as discussed in Rezaie et al. (2020), these models are also often vulnerable to over-correction. The regression method used by Rezaie et al. (2020) differs from previous regression-based techniques in that it does not assume a functional form for the impact of the survey properties on the observed galaxy density. Instead, Rezaie et al. (2020) rely on a neural network approach and feature selection to achieve accurate systematic corrections without over-correction. However, this method fails to propagate the statistical and systematic uncertainties due to the correction into the error budget of the galaxy clustering signal.

In this paper, we implement an improved version of the linear model described in Prakash et al. (2016). Relative to that work, we reduce the number of free parameters by one by enforcing the condition that in the absence of systematic fluctuations, the observed galaxy density field will be equal to the true galaxy density field with a mean of zero (i.e., we do not include the constant term in equations 13 and 14 of that paper as a free parameter in our model). Our analysis explicitly incorporates the spatial clustering signal of the galaxy density field in an iterative approach, and mock catalogs are used to calibrate and correct for the residual bias due to over-correction. The combination of using a Markov chain Monte Carlo (MCMC) to fit our model and utilizing mock catalogs to correct for the bias allows us to estimate both the statistical and systematic uncertainty of our systematics-corrected galaxy correlation function. Our procedure therefore correctly infates the error budget associated with the measurement of the galaxy correlation function, enabling us to trivially propagate these uncertainties into cosmological constraints downstream. We apply our model to the DES Y1 Gold redMaGiC catalog, and compare our results to those from Paper I and Abbott et al. (2018).

The paper is organised as follows: in section 2, we describe the redMaGiC catalog and the survey properties we use. We describe our method in section 3. The generation of our mock catalogs and the results of the validation in the mocks is discussed in section 4. We determine the impact of our systematics correction on the uncertainty in the correlation function in section 5. Our results are presented in section 6, and we summarize our findings in section 7.

| $z$ range | Y1 $N_{gal}$ (arcmin$^{-2}$) | Y1 $n_{gal}$ (arcmin$^{-2}$) | $N_{gal}$ | $n_{gal}$ (arcmin$^{-2}$) |
|----------|-------------------|-----------------|--------|------------------|
| 0.15 < $z$ < 0.3 | 63719 | 0.0134 | 61621 | 0.0134 |
| 0.3 < $z$ < 0.45 | 163446 | 0.0344 | 157800 | 0.0344 |
| 0.45 < $z$ < 0.6 | 240727 | 0.0506 | 231649 | 0.0505 |
| 0.6 < $z$ < 0.75 | 143324 | 0.0302 | 138450 | 0.0302 |
| 0.75 < $z$ < 0.9 | 42275 | 0.0089 | 40812 | 0.0089 |

Table 1. The redshift binning with information about the number of galaxies and number density both from the DES Y1 analysis and the current analysis. The second and fourth columns are the total number of galaxies in each of the redshift bins, while the third and fifth give the galaxy density per square arcminute. Note that there is a change in the mask in going from the Y1 counts and number density of columns two and three to our own in columns four and five, which reduces the area by ~3.5%.

2 DATA

We will estimate and correct for systematic-sourced fluctuations in the density of the DES Year 1 redMaGiC galaxy sample (Paper I). We use the same redshift binning as the Y1 analysis, shown here in table 1, along with the number count and galaxy density in each bin. As described in section 3, our analysis leads us to remove survey regions with large systematic-sourced fluctuations. This cut removes ~3.5% of the fiducial Y1 redMaGiC footprint, for a final area of $\sim1274$ square degrees. The counts and galaxy density after our systematic cut is shown in the fourth and fifth columns of table 1. Fig. 1 compares the redshift distributions in each bin before and after the systematics cuts. The gray lines are the distributions for the full redMaGiC sample, while the colored lines of the same style are the distributions in the same bin after cutting based on systematics. The distributions are not normalized, so differences in height are caused by the difference in the number of galaxies before and after the cut.

We estimate the galaxy correlation function using the Landy & Szalay (1993) estimator,

$$\hat{w}(\theta) = \frac{DD - 2DR + RR}{RR},$$

where $DD$, $DR$, and $RR$ are the number of pairs of galaxies with angular separation $\theta$ given a galaxy sample $D$ and a random catalog $R$. We measure the number of pairs using TreeCorr$^2$ (Jarvis et al. 2004), and our random catalog is the same one used by Paper I, except for the fact that we remove the random points in the survey regions excluded by our analysis.

We consider a total of 18 potential sources of systematics for the observed galaxy correlation function. Each of these is represented as a map which is pixelated on the sky using the HEALPix$^2$ (Górski et al. 2005) pixelization scheme. The majority of the maps we consider are imaging properties from the DES Y1 ‘GOLD’ catalog release (Drlica-Wagner et al. 2018). In each of the four bands (griz), we have maps of:

(i) total exposure time;
(ii) mean PSF FWHM;

1. http://ascl.net/1508.007
2. https://healpix.sourceforge.net
Figure 1. The redshift distribution for each redshift bin, found by stacking Gaussian distributions with mean and standard deviation equal to the redMaGiC redshift and error. The colored lines are the distributions with our new mask, and the gray dash-dotted lines are the corresponding distributions from Paper I. The lines are the distributions with our new mask, and the gray dash-dotted lines are the corresponding distributions from Paper I. The curves are not normalized, so differences in height are from the number of galaxies in the bin.

(iii) mean sky brightness, due to e.g. the moon; and
(iv) mean airmass.

For all mean quantities, the value on a pixel in a given band is computed as the weighted mean over all exposures in that band which contribute to the pixel. The exposure time is instead the sum of the exposure times for all exposures contributing to the pixel. Unlike Paper I, we do not include any depth maps, as these depend on the other imaging properties in a complicated way, and therefore are not linearly independent from the other imaging properties—including the depth maps would be double counting the other imaging properties and would likely increase any over-correction biases that might exist. We therefore have 16 imaging property maps. We also consider contamination due to foreground stars, for which we use the stellar density map described in section 5 of Paper I. Galactic extinction is included using the dust opacity map from the Planck Collaboration (Planck Collaboration 2014). Both stellar density and extinction were considered in Paper I, but were found to have no correlation with the galaxy density and thus were ultimately excluded from that correction. We include both here because we do not want to preclude the possibility that they could still add coherently with other potential sources of contamination and thus impact the observed galaxy density. Collectively, we refer to the set of 18 imaging property, stellar density, and Galactic extinction maps as “survey property maps”. Where necessary, we use the routines of healpy (Zonca et al. 2019) for manipulating both survey property and density maps.

3 METHOD

We determine the impact of observing conditions in the clustering of galaxies by relying on the spatial structure of the survey properties. Specifically, we estimate the extent to which the galaxy density maps are contaminated by systematic fluctuations by measuring the extent to which the galaxy density map traces the various survey property maps.

We begin by constructing a low-resolution ($N_{\text{side}} = 128$) map of the galaxy density field. This choice limits the number of empty pixels to a small percentage ($\leq 10\%$) of the total pixels. Working at this resolution, the average number of galaxies per pixel is $\geq 10$ at all redshifts.

We degrade the resolution of our survey property maps to match the resolution of our galaxy density map, properly accounting for the masked portions of every pixel. Specifically, the degraded survey property map $S'_j$ is related to the original survey property map $S$ via

$$S'_j = \sum_{i \in j} S_i f'_i,$$

where $f'_i \in [0, 1]$ is the fraction of pixel $i$ (at the original map resolution) that is detected in the footprint. The sums are over all high resolution pixels $i$ that fall within low resolution pixel $j$. We also degrade the pixel fraction map $f'_i$, such that the fraction $f''_j$ of low resolution pixel $j$ in the footprint is related to the high resolution fraction by

$$f''_j = \frac{1}{N} \sum_{i \in j} f'_i,$$

where $N$ is the number of high resolution pixels within a low resolution pixel.

The degraded survey property maps are used to compute standardized fluctuation maps as follows. Let $S'_\beta$ be the value of survey property map $\beta$ on low resolution pixel $j$. We define the mean $\bar{S}_\beta$ and fluctuation scale $\sigma_\beta$ of $S'_\beta$ via

$$\bar{S}_\beta \equiv \frac{1}{N_{\text{pix}}} \sum_{j=1}^{N_{\text{pix}}} S'_j,$$

and

$$\sigma_\beta \equiv 1.4826 \text{MAD}\left(S'_\beta\right).$$

The median absolute deviation in Eqn. (5) is

$$\text{MAD}\left(S'_\beta\right) \equiv \sum_{j=1}^{N_{\text{pix}}} \left| S'_j - \text{med}\left(S'_j\right) \right| / N_{\text{mask}}.$$

where $N_{\text{mask}}$ is the number of pixels not removed by the mask. The “fluctuation scale” $\sigma_\beta$ defined above is an estimator of the standard deviation for Gaussian fluctuations, but its value is more robust to outliers than estimates based on the sample variance. The standardized fluctuation map for survey property $\beta$ is defined as

$$S'_{\beta} \equiv \frac{S'_j - \bar{S}_\beta}{\sigma_\beta}.$$  

Rather than working with the fluctuation maps themselves, we construct an orthogonal map eigenbasis as follows. We assume the survey properties on each pixel are an independent random realization from an $N_{\text{maps}}$-dimensional distribution. We find the covariance matrix $C$ of the standardized maps at the fit resolution, where

$$C_{\alpha\beta} = \langle (S_\alpha - \langle S_\alpha \rangle)(S_\beta - \langle S_\beta \rangle) \rangle.$$
and $\langle \cdot \rangle$ is the spatial average over all observed pixels. We define the rotation matrix $R$ from the eigenvectors of $C$ such that

$$C = RDR^\top,$$

where $D$ is a diagonal matrix with the eigenvalues of $C$ along the diagonal. The rotated and standardized survey property value for map $\alpha$ on pixel $j$ is

$$s'_j = R^\top D \beta'_j.$$

(7)

Each $s'_j$ is, therefore, a linear combination of the fluctuations in the original SP maps $\{S'_j\}$ on a given pixel. For the rest of the paper, unless otherwise noted, the term “SP” refers to the fluctuations of the SPs. Thus, we write

$$\delta_{\text{sys}} = \delta_{\text{true}} + \delta_{\text{SV}} = \sum_{\alpha} a_\alpha s'_\alpha.$$

(8)

where the coefficients $a_\alpha$ are the derivatives of $\delta_{\text{obs}}$ with respect to $s_\alpha$ at $\{s'_\alpha\} = 0$. Note that any impact on the monopole of the galaxy density field by the survey properties gets absorbed into the mean observed galaxy density, and therefore has no impact on the galaxy fluctuations. Since our expansion is at first order, we can ignore the monopole as any impact with couplings to the linear perturbations would be second order. In the expansion, we have used the fact that

$$\delta_{\text{true}}' \{s'_\alpha\} = 0 = \delta_{\text{true}}' \{s'_\alpha\},$$

where $\delta_{\text{true}}$ is the true galaxy overdensity on pixel $j$. We have also assumed that the impact of SP on the galaxy density field is local: the SP in pixel $j$ only impact the galaxy density at pixel $j$.

Our task is to find the set of coefficients $\{a_\alpha\}$ in Eqn. (8). We do this by fitting the likelihood $P(\delta_{\text{obs}} | \tilde{\delta}_{\text{sys}})$ of the observed overdensity map given the systematics map $\tilde{\delta}_{\text{sys}} \equiv \sum_\alpha a_\alpha \tilde{\delta}_\alpha$, where the vector symbol denotes the full map. As discussed below, our procedure allows for covariance between pixels, so that this likelihood distribution does not in general reduce to a product over all pixels. We assume a Gaussian likelihood for $\delta_{\text{obs}}$. This explains why it is important for the mean number of galaxies in the galaxy density map to be large. We test our sensitivity to using a Gaussian distribution in section 4.2. The ensemble average over realizations of the observed density field at fixed systematics is simply

$$\langle \tilde{\delta}_{\text{obs}} \rangle = \tilde{\delta}_{\text{sys}}.$$

(9)

We can thus write our Gaussian likelihood for $\delta_{\text{obs}}$ as

$$\ln P(\tilde{\delta}_{\text{obs}} | \tilde{\delta}_{\text{sys}}) = -\frac{1}{2} \log |\Sigma_{\text{obs}}| - \frac{1}{2} (\tilde{\delta}_{\text{obs}} - \tilde{\delta}_{\text{sys}})^\top \Sigma_{\text{obs}}^{-1} (\tilde{\delta}_{\text{obs}} - \tilde{\delta}_{\text{sys}}).$$

(10)

where we have dropped all constant terms, and again

$$\tilde{\delta}_{\text{sys}} = \sum_\alpha a_\alpha \tilde{\delta}_\alpha.$$

(11)

The model parameters characterizing $\delta_{\text{sys}}$ are the coefficients $a_\alpha$ for each survey property, which we aim to recover from the data.

The covariance matrix for our likelihood can be written as the sum of two terms,

$$\Sigma_{\text{obs}} = \Sigma_{\text{PN}} + \Sigma_{\text{SV}}.$$

(12)

The first term contains the Poisson noise in the density field, and takes the form

$$\Sigma_{\text{PN}}_{jk} = \sigma_g^2 \delta_{jk}.$$

where $\sigma_g$ is a constant for which we can fit and $\delta_{jk}$ is the Kronecker delta. It will become clear shortly why we allow $\sigma_g$ to be an unknown constant, rather than fixing it to the Poisson expectation. The second term in Eqn. (12) accounts for the sample variance.

We fit for our SP coefficients in two iterations. During the first iteration, we assume there is no sample variance, so that $\Sigma_{\text{obs}}$ is diagonal. In this case, we can analytically solve for the variance $\sigma_g^2$ and coefficients $\{a_\alpha\}$ that minimize the likelihood in Eqn. (10) by solving the simultaneous set of equations obtained when setting all of the partial derivatives with respect to the survey parameter coefficients $a_\alpha$ to zero. We are also able to find the $19 \times 19$-dimensional parameter covariance matrix analytically as the inverse of the Hessian matrix evaluated at the minimum— we use this parameter covariance matrix (excluding the row and column corresponding to $\sigma_g^2$) in the second iteration to select random starting locations within the 18-dimensional parameter space.

Once we complete our first iteration, we use our results to estimate $\delta_{\text{true}}$. We then define $\Sigma_{\text{SV}}$ via

$$\Sigma_{\text{SV}}_{jk} = (1 - \delta_{jk}) w_{\text{true}}(\ell_{jk}),$$

where $w_{\text{true}}$ is the correlation function of our estimated true overdensity field $\delta_{\text{true}}$ and $\delta_{jk}$ is the angular separation between pixels $j$ and $k$. We artificially set the diagonal elements of $\Sigma_{\text{SV}}$ to zero because we cannot differentiate between the sample variance and Poisson noise within a single pixel. This also explains why we treated $\sigma_g$ as an unknown constant: $\sigma_g$ is really the sum of the Poisson and zero-offset sample variance terms. We therefore continue to use the $\sigma_g$ obtained from the minimization in the first iteration as the only term on the diagonal of $\Sigma_{\text{obs}}$ in the second iteration.

We use the resulting “Poisson” and sample variance noise estimates to refit for the coefficients of each of the SP parameters. In the second iteration, we use a Markov Chain Monte Carlo (MCMC) algorithm (specifically emcee; Foreman-Mackey et al. 2013) to sample our parameter space and estimate the posterior distribution. Our best fit coefficients after the second iteration are the mean parameter values from the chain. We check for convergence, we look at the

3 We run our chain with 36 walkers for 1000 steps each. We do not use a burn-in when fitting to the real data as we generate the initial positions by drawing from a multivariate Gaussian with a
shift in the coefficients between the first and second halves
of each chain relative to the error from the chain. We find
a median shift (over all 18 parameters) of 0.19, 0.29, 0.18,
0.26, and 0.14 for redshift bins 1 through 5 respectively,
and the worst convergence in any single parameter for each
redshift bin is 0.60, 0.72, 0.55, 0.53, and 0.34. We have
verified that using the coefficients from the second iteration
to update $\Sigma^{\text{SV}}$ and performing a second MCMC (i.e. getting
a third iteration of the coefficients) does not have a significant
impact on our results.

Once we have our coefficients, we correct for the effect
of systematic fluctuations on the correlation function. We
do so by defining weights for each galaxy based on the
systematics map value on the pixel containing the galaxy. For
calculating galaxy weights, we use the systematics map at a
resolution of $N_{\text{side}} = 4096$. While we must fit at low resolu-
tion to ensure that our likelihood is roughly Gaussian, the
fundamental assumption of our method is that survey prop-
ties only produce local modulations of the galaxy density
field. Since our model is linear, all the local modulations
add together when smoothing to go to lower resolution, so
the relation between the survey properties and the galaxy
density must be the same at low and high resolution. We
standardize and rotate the high resolution maps as we did
with the low resolution maps, but we use the mean, fluc-
tuation scale, and rotation matrix determined from the low
resolution maps for the purposes of defining the high reso-
nution eigen-maps. This is critical, as the definition of the
maps must match that employed in our fits. The weight for
a galaxy on high-resolution pixel $i$ is

$$w_i = \frac{1}{1 + \sum a_i^2 r_i^2}. \quad (13)$$

We refer to the correlation function measured using these
weights as $w_{\text{corr}}$. As previously mentioned, when calculat-
ing the systematics-corrected correlation function, we also
exclude any galaxies on pixels with $\delta_{\text{sys}} > 0.2$. This should
restrict us to only areas of the sky where our first order
approximation is valid. The resulting footprint is $\sim 3.5\%$
harder than the original Y1 footprint, and a total of 23,359
galaxies are removed across all redshift bins.

The above procedure tends to over-correct the data
for the impact of SPs. We calibrate the amount of over-
correction in the correlation function from our method using
mock galaxy catalogs, and use these to de-bias our proce-
duce, which will result in an updated systematics-corrected
relation function estimate $w_{\text{corr}}$. The details of this de-
biasing are presented in the next section. We describe how
we incorporate statistical and systematic uncertainties due
to our correction in the error budget of the observed corre-
lation function in section 5.

4 METHODOLOGY VALIDATION WITH
MOCK CATALOGS

There are three potential sources of systematic bias in our
analysis. These are, in no particular order, (i) the first order
mean and covariance matrix given by the coefficients and param-
eter covariance from the first iteration. We use a burn-in of 300
steps per walker when fitting to mock catalogs.

To create our log-normal mock catalogs, we use the fidu-
cial cosmological parameters from Paper I: $\Omega_m = 0.295,$
$A_s = 2.260574 \times 10^{-9},$ $n_s = 0.0468,$ $h = 0.6881,$
and $\sigma_8 = 0.9676.$ We run CAMB (Lewis et al. 2000; Howlett et al. 2012)
and Halofit_Takahashi (Smith et al. 2003; Takahashi et al.
2012) using CosmoSIS (Zuntz et al. 2015) to compute the
angular galaxy clustering power spectrum. We then use this
power spectrum to generate a log-normal random field for
the true galaxy over-density, $\delta_{\text{true}}$, in each of our five redshift
bins via the code psydocl. This galaxy density field is gener-
at high resolution ($N_{\text{side}} = 4096$). When appropriate
(see below), we add systematic fluctuations to the galaxy density field using
our linear model. We then calculate the expected number
of galaxies in each pixel, taking into account the masked
fraction in each pixel. Finally, we randomly place $N$ galaxies
within each pixel, where $N$ is a Poisson realization of the
expected number of galaxies.

For each redshift bin, each realization is then used to create
two mock catalogs, one with no SP contamination and an-
other with SP applied using the best fit coefficients from our
analysis of the DES Y1 data set. We refer to these as un-
contaminated and contaminated mocks, respectively. Note that
while both the uncontaminated and contaminated mocks
share the same underlying over-density fields, they have dif-
ferent Poisson realizations.

We use our methodology from section 3 to estimate the
impact of SPs in our mock galaxy catalogs, and compare
the resulting corrected correlation function to the underly-
ing true mock galaxy correlation function. To increase com-
putational efficiency, we restrict our mock catalogs to the
final mask employed in our analysis of the DES Y1 galax-
ies. That is, we do not re-apply the $\delta_{\text{sys}} \leq 0.2$ cut in every
mock. Doing so would have forced us to recompute random
pairs for every mock due to slight differences in the final
footprint. Because systematic fluctuations are linear in the
mock catalog by construction, this additional restriction has
no bearing on the conclusions drawn from our simulations.
Unfortunately, this also means our mock catalogs do not
allow us to test how sensitive our method is to non-linear
contamination.

We test whether our contaminated mock galaxy cata-
logs have comparable levels of SP contamination to the data

\footnote{https://bitbucket.org/niallm1/psydocl/src/master/}
as follows. For the data and both sets of mock galaxy catalogs we compute the raw observed correlation function, and the corrected correlation function $w_{\text{corr}0}$ as described in section 3. We then calculate the difference between these two correlation functions in all three cases.

The blue solid line in Fig. 2 shows the biased systematic correction of the DES Y1 redMaGiC data computed using the first iteration of our method, while the orange dashed line is the mean correction from the 100 contaminated mock galaxy catalogs. The green dashed-line is the mean of the uncontaminated mocks. Therefore, Fig. 2 provides evidence that the contaminated mocks is comparable to that in the data, particularly for the redshift bins that exhibit strong systematic fluctuations in the DES Y1 data set. More generally, the correction derived from our contaminated mocks is comparable to that in the data, particularly for the redshift bins which exhibit strong systematic fluctuations. Thus, Fig. 2 provides evidence that the contaminated mock galaxy catalogs used in our analysis are a reasonable match to the data.

### 4.2 Methodology Validation: Recovery of the SP Coefficients

We fit for the SP coefficients in both sets of 100 mocks for each redshift bin, for a total of 1000 independent mock catalogs to be analyzed. Because we know the SP coefficients used to generate the mocks, we can test whether we correctly recover the input coefficients with our analysis. To do so, we calculate the $\chi^2$ of the mean coefficients estimated from our posterior and the input for each mock. That is, for each mock catalog $\nu$ we compute

$$\chi^2_{\nu} = (\{\hat{a}_\alpha\}_\nu - \{a_\alpha\}_0)^T \hat{C}_\nu^{-1} (\{\hat{a}_\alpha\}_\nu - \{a_\alpha\}_0),$$  \hspace{1cm} (14)$$

where $\{a_\alpha\}_\nu$ is the input vector of 18 coefficients used in generating mock catalog $\nu$, $\{\hat{a}_\alpha\}_\nu$ is the mean vector of the posterior from our analysis for mock $\nu$ with length 18, and $\hat{C}_\nu$ is the parameter covariance matrix estimated from the MCMC chain for mock $\nu$ with dimensions $18 \times 18$. We show the distribution of the $\chi^2$ statistics for all 1000 mocks as the blue histogram in Fig. 3. For reference, the green line is the expected $\chi^2$ distribution for 18 degrees of freedom, 18 being the number of SPS. It is clear that the distribution of $\chi^2$ values is biased relative to our expectation.

Hartlap et al. (2007) pointed out that noise in the covariance matrix biases $\chi^2$ statistics. In our case, the noise in the covariance matrix is only partly due to a finite number of realizations in the MCMC: noise in the data will also generate noise in the empirically estimated covariance matrix, which will in turn bias the recovered $\chi^2$. In the absence of a first principles prescription for the expected bias in our analysis, we adopt an ad-hoc correction by demanding the average $\chi^2$ over all our simulations be equal to the number of degrees of freedom in the problem (18). That is, we de-bias every $\chi^2$ value by dividing it by the factor $d = 22.33/18 = 1.24$. The resulting distribution is shown as the orange histogram in Fig. 3, which is now an excellent match to expectations.

As discussed in Hartlap et al. (2007), the bias due to noise in the covariance matrix estimate propagates into the parameter posteriors. Consequently, we increase the statistical uncertainty in our recovered corrections for the correlation function by a factor of $\sqrt{1.24}$. The fact that our recovered distribution of $\chi^2$ values matches expectation implies that we are successfully recovering the input systematic coefficients within our re-scaled noise estimate.

### 4.3 Over-correction Calibration

The orange dashed line and shaded band in Fig. 4 show the mean and 1σ region for the difference between the observed and true correlation functions of our 100 independent systematics-contaminated mock catalogs, in units of the statistical uncertainty of the DES Y1 analysis. The 1σ region is computed as the error on the mean. The blue solid line and shaded band are the same as the orange, but for the systematics-corrected correlation function with no bias correction (i.e. $w_{\text{corr}}$). While there is a significant improvement when going from no correction to our systematics correction, it is also clear that our method somewhat over-corrects the data.

We seek to calibrate the amount of over-correction for our method based on the results from Fig. 4. However, note that the level of over-correction is itself sensitive to the input amount of contamination. This is apparent in Fig. 5, which shows the mean and error on the mean of the over-correction for both uncontaminated (orange) and contaminated (blue) mock galaxy catalogs.

We use the results in Fig. 5 to reduce the impact of over-correction, and to characterize the remaining systematic uncertainty associated with this effect. Because we see that the level of over-correction is sensitive to the amount of contamination and we do not know the actual contamination level in the data, we must account for this sensitivity when we de-bias. The contaminated and uncontaminated mocks represent the two extreme possibilities for the data, so we de-bias our correlation functions using the mean of the over-correction measured in the contaminated and uncontaminated mocks. That is, we define

$$\Delta w(\theta) = \frac{1}{2} \left[ \langle w_{\text{corr}}^{\text{cont}}(\theta) - w_{\text{true}}(\theta) \rangle + \langle w_{\text{corr}}^{\text{uncont}}(\theta) - w_{\text{true}}(\theta) \rangle \right],$$  \hspace{1cm} (15)$$

where $w_{\text{corr}}^{\text{cont}}(\theta)$ is the systematics-corrected correlation function at $\theta$ for the contaminated mock galaxy catalogs prior to de-biasing, and $w_{\text{corr}}^{\text{uncont}}$ is the equivalent quantity computed for the uncontaminated mock galaxy catalogs. The average $\langle \cdot \rangle$ above is over the simulated data sets. Given $\Delta w$, we define an updated systematics-corrected correlation function $w_{\text{corr}1}$ via

$$w_{\text{corr}1}(\theta) \equiv w_{\text{corr}}(\theta) - \Delta w(\theta).$$  \hspace{1cm} (16)$$

The green dash-dotted line and shaded band in Fig. 4 show the mean and 1σ region for the difference between our updated systematics-corrected correlation function estimates $w_{\text{corr}1}$ and the true correlation function, as estimated using 100 contaminated mock catalogs. Recall that the y-axis is scaled in units of the purely statistical uncertainty of the DES Y1 analysis. It is clear from the figure that while a residual bias remains, the amplitude and uncertainty is much smaller than the statistical uncertainties for the DES Y1.
data set. Moreover, the true underlying correlation function is within the expected errors in the measurement.

5 THE IMPACT OF SYSTEMATICS

The covariance matrix used in Paper 1 when fitting the galaxy clustering signal was solely based upon theoretical considerations, as described in Krause & Eifler et al., (2017). In particular, it accounted only for Poisson noise and sample variance in the galaxy density field, where the latter includes both Gaussian and connected terms, as well as the super-sample covariance contribution. In practice, removing the imprint of systematic fluctuations on the galaxy density field carries with it additional uncertainty that needs to be propagated into the covariance matrix used to analyze the data. We now characterize this additional noise contribution.

We start with the statistical uncertainty in our method. Because we use an MCMC to fit for the coefficients describing the impact of SPs, we can readily sample the posterior distribution to arrive at the statistical uncertainty in our corrections. Specifically, we draw \( N_{\text{real}} \) random samples from our MCMC chain on the data, and calculate the systematics-corrected correlation function \( w_{\text{corr}} \) for each of these realizations of the SP coefficients. We calculate the covariance matrix of the correlation function from these realizations, and re-scale it by the factor of \( \langle \chi^2 \rangle / 18 = 1.24 \) from the discussion in section 4.2. This defines the statistical covariance matrix \( C_{\text{stat}} \) which characterizes statistical uncertainties in the systematics correction.

The systematic uncertainty associated with our debiasing procedure of section 4.3 is calculated as the sum in quadrature of two distinct terms. The first term sets the systematic uncertainty to half the amplitude of the applied correction, i.e. large corrections will result in large uncertainties. The second term accounts for the difference in the amount of over-correction inferred from the contaminated and uncontaminated mocks. If the inferred over-corrections are vastly different, the resulting mean correction should be assigned a large uncertainty. This uncertainty is set to half the difference between the over-correction inferred from the contaminated and uncontaminated mocks. The corresponding covariance matrix characterizing these systematic uncertainties takes the form

\[
C_{\text{sys}}^{ab} = \frac{1}{4} [\Delta w(\theta_a) \Delta w(\theta_b) + \delta w(\theta_a) \delta w(\theta_b)] .
\]

\( \Delta w(\theta) \) and \( \delta w(\theta) \) are the over-corrections and uncertainties of the systematics correction, respectively.
Figure 3. The distribution of $\chi^2$, as defined in Eqn. (14), for all contaminated and uncontaminated mocks in all redshift bins. The blue histogram is the original distribution. The orange histogram is the result of re-scaling every $\chi^2$ by $\theta/(\chi^2)$. The green line is the expected $\chi^2$ distribution with 18 degrees of freedom, for reference. Note that both histograms are normalized.

where $a$ and $b$ index angular bins, and where we have defined

$$\delta w(\theta) = \frac{1}{2} \left[ \langle w_{\text{cont}}(\theta) - w_{\text{true}}(\theta) \rangle - \langle w_{\text{uncorr}}(\theta) - w_{\text{true}}(\theta) \rangle \right] .$$

As in Eqn. (15), the average $\langle \cdot \rangle$ above is over all simulated data sets.

The final covariance matrix estimate for the data is $C^{\text{Y1}} + C_{\text{sys}}$, where $C^{\text{Y1}}$ is the theoretical covariance matrix used in Paper I. The green dash-dotted line and band in Fig. 6 show the mean and uncertainty of the ratio between the diagonal elements of $C^{\text{Y1}}$, as defined in Eqn. (17), to the diagonal elements of $C^{\text{Y1}}$. The orange dashed line and band is the same ratio but for $C_{\text{stat}}$. We have checked that increasing the number of realizations used to estimate $C_{\text{stat}}$ does not significantly change our measured covariance. The combination of the systematic and statistical covariance relative to the Y1 covariance is shown as the blue solid line and band. The gray shaded region in each panel shows the region excluded by the small scale cuts for the cosmology analysis in Paper I, for which our changes will not impact the inferred cosmological parameters. While uncertainties in our de-biasing procedure for over-correction are negligible, we see that the statistical uncertainties in our systematics mitigation algorithm start to become comparable to statistical uncertainties in the correlation function at large scales.

6 RESULTS

As a brief summary of sections 3, 4 and 5, we assume fluctuations in SPs introduce artificial galaxy fluctuations through a local linear response. We calibrate these response coefficients using the observed galaxy density maps and SP maps, and use them to remove the impact of systematic fluctuations in the galaxy density field. Using mock galaxy catalogs, we demonstrate that our method results in some small amount of over-correction, which we calibrate. We further characterize the additional statistical and systematic uncertainty introduced by our systematics-mitigation algorithm. We now apply our full systematics-correction algorithm to the DES Y1 data set.

In Fig. 7, we show the angular correlation function in each of the five redshift bins using our systematics weights and bias correction as blue circles, with errors from the combined $C^{\text{Y1}} + C_{\text{sys}} + C_{\text{stat}}$ covariance matrix. For comparison, we also show the correlation function without correction and the systematics-corrected correlation function from Paper I. We note that in arriving at our updated correlation function, there is a small change in the mask to mitigate the impact of non-linear systematic fluctuations, so that the areas over which the correlation functions are computed are not precisely the same. The bottom panel in each figure shows the difference of each of the correlation function relative to the systematics-corrected estimate of Paper I. We see that the two different methods for estimating systematic corrections are in excellent agreement relative to the statistical uncertainty of the DES Y1 data set. Nevertheless, some small differences are clearly present. It is interesting to note that in the second redshift bin, our correction results in slightly more correlation than the uncorrected correlation function, rather than less. This boost is due to the over-correction de-biasing procedure calibrated in the mocks.

To quantify the difference in the correlation functions from the two different weighting methods, table 2 shows the $\chi^2$ statistic for the DES Y1 correlation function and our correlation function, namely

$$\chi^2 = (w_{\text{Y1}}(\theta) - w_{\text{corr}}(\theta))^\top C^{-1} (w_{\text{Y1}}(\theta) - w_{\text{corr}}(\theta)),$$

where the choice of covariance matrix $C$ used requires some discussion (see below). In calculating $\chi^2$, we exclude any angular bins that are removed with the small scale cut (the gray regions in Fig. 7). The number of remaining angular bins after the small scale cut is shown in the last column of the table. The difference between the correlation functions should not be subject to Poisson noise or sample variance, as these are the same for both correlation functions. Therefore, in the second column of table 2, we show the $\chi^2$ when we use $C = C_{\text{stat}} + C_{\text{sys}}$. While in principle this comparison should also be subject to the uncertainty due to the method.
of Paper I, that paper demonstrated that the uncertainties in their systematics correction didn’t impact the cosmological priors and therefore those uncertainties were not characterized. Consequently, our comparison does not account for the uncertainty in the Y1 systematics correction. It is clear that our weights method results in a correlation function that is formally inconsistent with that of the Y1 analysis assuming zero uncertainty from the Y1 weights method. However, the size of the cosmology contours is sensitive to the full covariance matrix $C_{Y1} + C_{stat} + C_{sys}$. The third column in table 2 shows the $\chi^2$ when we use the full covariance matrix for $C$. Notice that in this case, the $\chi^2$/dof $\leq 0.1$ for most redshift bins. This result explicitly demonstrates that the difference in the correlation function produced by the two methods is small relative to the statistical uncertainty.

We use our new de-biased systematics-corrected correlation function and full $C_{Y1} + C_{stat} + C_{sys}$ covariance matrix in combination with the cosmic shear and galaxy-galaxy lensing data vectors and covariance matrices from the DES Y1 cosmology analysis (Abbott et al. 2018) to re-run the DES 3x2pt cosmology analysis. The resulting cosmology contours for $S_8$, $\Omega_m$, and $\sigma_8$ are shown in blue in Fig. 8. For our analysis, we use an updated version of Cosmolike (Krause & Eisen 2017; Fang et al. 2020) and use emcee (Foreman-Mackey et al. 2013) as our sampler. The result with this pipeline and our updated data vector and covariance matrix are shown in red in Fig. 8.

As we use a different pipeline and sampler than the fiducial Y1 analysis of Abbott et al. (2018), it is unclear how much of the difference between the red and blue contours in Fig. 8 is because of our changes to the data vector and covariance matrix and how much is a reflection of the differences in the modelling pipeline. We therefore show as black dashed lines in Fig. 8 the results of using the updated Cosmolike pipeline when run on the fiducial Y1 data vector and covariance matrix. The differences between the red and black contours are due to the difference in the estimated correlation function and its corresponding covariance matrix. It is clear that our weighting method does not have a significant impact on the cosmological inference relative to the Y1 analysis. This is expected given that both the difference in the correlation functions with the two different weighting methods and the uncertainty in our systematic correction are small relative to the statistical uncertainty of the measurement.

The black and red text above the histogram of $S_8$ in Fig. 8 show the minimum $\chi^2$ values for the fiducial Y1 data vector and our updated data vector, respectively, for each data vector compared to the model with 444 degrees of freedom (see Abbott et al. 2018). The minimum $\chi^2$ in each case
is \(-2 \log L_{\text{max}}\) at the maximum likelihood point in the MCMC chain. It is encouraging to see that even though our method does not significantly change the cosmological inference, it does result in a significant improvement in the goodness of fit (\(\Delta \chi^2 \approx -6.5\) with no additional parameters). This improvement in the \(\chi^2\) is due to both the increased error from our systematics correction and the shifts in the data vector that occur when replacing the Y1 weighting method with ours. To show that this is the case, we consider the calculation of the best fit \(\chi^2\) with our updated data vector and covariance matrix, which we now write as

\[
\chi^2_{\text{new}} = \left( \bar{\delta}_{Y1} + \Delta - \bar{m}_{Y1} \right)^\top \left( C^{Y1} + \delta C \right)^{-1} \left( \bar{\delta}_{Y1} + \Delta - \bar{m}_{Y1} \right),
\]

where \(\bar{\delta}_{Y1}\) is the original data vector from the Y1 analysis, \(\bar{m}_{Y1}\) is the best fit model vector from the original Y1 analysis, \(\delta C \equiv C^{\text{cov}\text{st}} + C^{Y1}\) is the change in the covariance matrix, and \(\Delta\) is the change to the difference between the data vector and best fit model vector introduced by our weights method. Note that this means that \(\Delta\) is sensitive to both the change in the data vector as well as changes to the best fit parameters. We can expand this equation around \(\delta C = 0\), dropping terms that are beyond first order in \(\delta C\) as well as terms involving \(\tilde{\Delta} \delta C\). Doing so, we find

\[
\Delta \chi^2 \approx \tilde{\Delta}^\top \left( C^{Y1} \right)^{-1} \left[ 2 \left( \bar{\delta}_{Y1} - \bar{m}_{Y1} \right) + \tilde{\Delta} \right] - \left[ \left( C^{Y1} \right)^{-1} \left( \bar{\delta}_{Y1} - \bar{m}_{Y1} \right) \right]^\top \Delta C \left( C^{Y1} \right)^{-1} \left( \bar{\delta}_{Y1} - \bar{m}_{Y1} \right).
\]

The first term in this expression gives the \(\Delta \chi^2\) resulting from changing the data vector and the difference in the resulting best fit model vector. The second term is the \(\Delta \chi^2\) caused by the change to the covariance matrix from our systematics correction. We find \(\Delta \chi^2 \approx -3.6\) for the first term and \(\Delta \chi^2 \approx -3.2\) for the second. From this, we conclude that both the shift in the data vector (and resulting shift in the best fit) and the increased uncertainty due to our systematics correction contribute to the improvement in the fit.

7 CONCLUSIONS

We have presented a method for using a linear model to mitigate the effect of systematic fluctuations in galaxy clustering analyses due to observing conditions. Our method uses a Gaussian likelihood to fit the linear model to the observed galaxy over-density and SP maps on each pixel. Our analysis explicitly incorporates the fact that neighboring pixels in the sky are correlated using an iterative approach: our
first iteration uses a diagonal covariance matrix, while the second builds a non-diagonal covariance matrix from the systematics-corrected correlation function estimated from the first iteration. We further use mock catalogs to calibrate the remaining over-correction bias, which we then remove from the data correlation function.

We apply our methodology to the DES Y1 redMaGiC data set. Our method has four important advantages relative to that adopted in the DES 3x2pt analysis presented in Abbott et al. (2018), namely:

- Our method does not require that decisions be made with regards to which survey properties matter and which don’t. This also allows for the possibility of multiple survey properties “conspiring” to create an observationally significant signal without any single systematic reaching that threshold.
- Our method properly increases the error budget of the galaxy correlation function estimate by accounting for the statistical and systematic uncertainty associated with systematic mitigation. We have found doing so non-trivially impacts the goodness-of-fit statistic of the best fit cosmological model.
- Our method explicitly incorporates clustering information from neighboring pixels in our calibration of the impact of survey properties on the galaxy density field.
- Our method is fully automated: it can be run from start to finish with minimal supervision, enabling for quick turn around for future data sets, with no extra tuning.

While our updated systematics-corrected correlation function in the DES Y1 data set is formally inconsistent with that of Paper I, the two are in good agreement relative to the level of statistical uncertainty in DES Y1. Because the statistical uncertainty in the measurement is larger than the uncertainty in our correction, we observe no significant impact on the cosmological inference using a data vector with our systematics weights relative to the Y1 3x2pt cosmology analysis. Encouragingly, however, we do see an improvement in the goodness of fit, which is caused by both the change to the data vector with our new weights and the increased error from our systematics correction. We also expect the difference in the data vector and the uncertainty in the correction to become more important in the near future as the large number of galaxies observed by upcoming surveys de-
Figure 7. The correlation function in each redshift bin for the DES Y1 redMaGiC galaxies. The gray dashed line is the correlation function without correcting for SPs. The orange solid line is the systematics-corrected correlation from Paper I. The blue points are the de-biased correlation function using our linear model weights, and the error bars are obtained from the full \((C_{Y1} + C_{\text{stat}} + C_{\text{sys}})\) covariance matrix. Note that while the gray and orange lines are computed with the DES Y1 mask, the blue points use our restricted mask with \(\delta_{\text{sys}} \leq 0.2\), resulting in \(-3.5\%\) less area.

increases the statistical uncertainty in galaxy clustering measurements.
