Primordial Hypermagnetic Knots

Massimo Giovannini

Department of Physics and Astronomy, Tufts University, Medford, Massachusetts 02155, USA

Topologically non-trivial configurations of the hypermagnetic flux lines lead to the formation of hypermagnetic knots (HK) whose decay might seed the Baryon Asymmetry of the Universe (BAU). HK can be dynamically generated provided a topologically trivial (i.e. stochastic) distribution of flux lines is already present in the symmetric phase of the electroweak (EW) theory. In spite of the mechanism generating the HK, their typical size must exceed the diffusivity length scale. In the minimal standard model (MSM) (but not necessarily in its supersymmetric extension) HK are washed out. A classical hypermagnetic background in the symmetric phase of the EW theory can produce interesting amounts of gravitational radiation.

Topologically non-trivial configurations of the magnetic field lines are allowed in terrestrial tokamaks and astrophysical plasmas [1]. The presence of HK in the symmetric phase of the EW theory (i.e. $T > T_c$) cannot be theoretically excluded. Since the conductivity $\sigma$, of the EW plasma is typically large, in analogy with the electromagnetic case, we can expect that the topological structure of the hypermagnetic flux lines will be approximately conserved (up to corrections of order $1/\sigma_c$) for sufficiently large scales. The importance of the topological properties of long-range (Abelian) hypercharge magnetic fields has been stressed in the past [2,3]. In [4] it was argued that if the spectrum of hypermagnetic fields is dominated by parity non-invariant Chern-Simons (CS) condensates, the BAU could be the result of their decay. Most of the mechanisms often invoked for the origin of condensates, the BAU could be the result of their decay. The purpose of this Letter is to connect the topological properties of the HK to the generation of the BAU. We show that HK can be dynamically generated and can seed the BAU only if the correlation scale of the knot is larger than the diffusivity scale. We exclude this possibility in the MSM. Since hypermagnetic fields present in the symmetric phase of the EW theory can radiate gravitational waves (GW), we propose possible phenomenological tests of our generation mechanism.

Suppose that the EW plasma is filled, for $T > T_c$ with topologically trivial hypermagnetic fields $\mathcal{H}_Y$, which can be physically pictured as a collection of flux tubes (closed because of the transversality of the field lines) evolving independently without breaking or intersecting with each other. If the field distribution is topologically trivial (i.e. $\langle \mathcal{H}_Y \cdot \nabla \times \mathcal{H}_Y \rangle = 0$) parity is a good symmetry of the plasma and the field can be completely homogeneous. We name hypermagnetic knots those CS condensates carrying a non vanishing (averaged) hypermagnetic helicity (i.e. $\langle \mathcal{H}_Y \cdot \nabla \times \mathcal{H}_Y \rangle \neq 0$). If $\langle \mathcal{H}_Y \cdot \nabla \times \mathcal{H}_Y \rangle \neq 0$ parity is broken for scales comparable with the size of the HK, the flux lines are knotted and the field $\mathcal{H}_Y$ cannot be completely homogeneous.

In order to seed the BAU a network of HK should be present at high temperatures [4]. In fact for temperatures larger than $T_c$ the fermionic number is stored both in HK and in real fermions. For $T < T_c$, the HK should release real fermions since the ordinary magnetic fields (present after EW symmetry breaking) do not carry fermionic number. If the EWPT is strongly first order the decay of the HK can offer some seeds for the BAU generation [4]. This last condition can be met in the minimal supersymmetric standard model (MSSM) [7]. Under these hypotheses the integration of the $U(1)_Y$ anomaly equation [4] gives the CS number density carried by the HK which is in turn related to the density of baryonic number $n_B$ for the case of $n_f$ fermionic generations

$$\frac{n_B}{s} (t_c) = \frac{\alpha'}{2 \pi \sigma_c s} \frac{n_f \langle \mathcal{H}_Y \cdot \nabla \times \mathcal{H}_Y \rangle M_0 \Gamma}{\Gamma + \Gamma_H T_c^2}, \quad \alpha' = \frac{g^2}{4\pi} \quad (1)$$

($g'$ is the $U(1)_Y$ coupling and $s = (2/45)\pi^2 N_{eff} T^3$ is the entropy density; $N_{eff}$ is the effective number of massless degrees of freedom at $T_c$ [106.75 in the MSM]; $M_0 = M_{P}/1.66\sqrt{N_{eff}} \approx 7.1 \times 10^{17}$GeV). In Eq. ($1$) $\Gamma$ is the perturbative rate of the right electron chirality flip processes (i.e. scattering of right electrons with the Higgs and gauge bosons and with the top quarks because of their large Yukawa coupling) which are the slowest reactions in the plasma and

$$\Gamma_H = \frac{783}{22} \frac{\alpha'^2}{\sigma_c \pi^2 \frac{|\mathcal{H}_Y|^2}{T_c^2}} \quad (2)$$

is the rate of right electron dilution induced by the presence of a hypermagnetic field. In the MSM we have that $\Gamma < \Gamma_H$ [4] whereas in the MSSM $\Gamma$ can naturally be larger than $\Gamma_H$. Unfortunately, in the MSM a hypermagnetic field can modify the phase diagram of the phase transition but cannot make the phase transition strongly first order for large masses of the Higgs boson [4]. Therefore, we will concentrate on the case $\Gamma > \Gamma_H$ and we will show that in the opposite limit the BAU will
be anyway small even if some (presently unknown) mechanism would make the EWPT strongly first order in the MSM.

HK can be dynamically generated. Gauge-invariance and transversality of the magnetic fields suggest that perhaps the only way of producing $(\mathcal{H}_Y \cdot \vec{\nabla} \times \mathcal{H}_Y) \neq 0$ is to postulate, a time-dependent interaction between the two (physical) polarizations of the hypercharge field $Y_\alpha$. Having defined the Abelian field strength $F_{\alpha\beta} = \nabla_\alpha Y_\beta$ and its dual $F^{\alpha\beta}$ such an interaction can be described, in curved space, by the Lagrangian \[ L_{\text{eff}} = \sqrt{-g} \left[ -\frac{1}{4} F_{\alpha\beta} F^{\alpha\beta} + c \frac{\sigma}{4M} Y_{\alpha\beta} Y^{\alpha\beta} \right], \] (3)

where $g_{\mu\nu}$ is the metric tensor and $g$ its determinant, $c$ is the coupling constant and $M$ is a typical scale. This interaction is plausible if the $U(1)_Y$ anomaly is coupled, (in the symmetric phase of the EW theory) to dynamical pseudoscalar particles $\psi$ (like the axial Higgs of the MSSM). Thanks to the presence of pseudoscalar particles, the two polarizations of $\mathcal{H}_Y$ evolve in a slightly different way producing, ultimately, inhomogeneous HK.

Suppose that an inflationary phase with $a(\tau) \sim \tau^{-1}$ is continuously matched, at the transition time $t_1$, to a radiation dominated phase where $a(\tau) \sim \tau$. Consider then a massive pseudoscalar field $\psi$ which oscillates during the last stages of the inflationary evolution with typical amplitude $\psi_0 \sim M$. As a result of the inflationary evolution $|\nabla \psi| \ll \psi$. Consequently, the phase of $\psi$ can get frozen \[ 0. \] Provided the pseudoscalar mass $m$ is larger than the inflationary curvature scale $H_1 \sim \text{const.}$, the $\psi$ oscillations are converted, at the end of the quasi-de Sitter stage, in a net helicity arising as a result of the different evolution of the two (circularly polarized) vector potentials

\[
Y'' + \sigma Y' + \omega^2 Y = 0, \quad \mathcal{H}_Y = \vec{\nabla} \times \vec{Y} \\
\psi \sim a^{-3/2} \psi_0 \sin \left[ \frac{m(t-t_1)}{2} \right], \quad \omega^2 = k^2 + \frac{c}{M} a \psi,
\]

where we denoted with $\vec{H}_Y = a^2 \mathcal{H}_Y$ the curved space fields and with $\sigma = \sigma_c a$ the rescaled hyperconductivity; the prime denotes derivation with respect to conformal time $\tau$ whereas the over-dot denotes differentiation with respect to cosmic time $t$). Since $\omega_+ \neq \omega_-$ the helicity gets amplified according to Eq. (4) and the BAU can be obtained (for $\Gamma > \Gamma_H$) from Eq. (5)

\[
\frac{n_B}{s} = \delta \left( \frac{m}{H_i} \right)^5 \left( \frac{H_i}{M_P} \right)^7 e^{(\frac{\omega_m}{T_c})^2} e^{-2(\frac{\omega_m}{T_c})^2} \\
\delta = \frac{45 g \sigma^2 n_f N_{eff}^2 M_0}{512 \pi^2 \sigma_0} \frac{1}{T_c}, \quad \sigma_0 = \frac{\sigma_c}{T_c},
\]

where $\omega_m = k_m/a \sim (c/2)(\psi_0/M)m$ is the maximally amplified frequency corresponding to the center of the first (and larger) instability band of the Mathieu-type equation for $Y_\pm$ and $\omega_+(t) \sim \sigma_c^{1/2} N_{eff}^{1/4} (T_c/M_P)^{1/2} T_c$ is the maximal (hyperconductivity) frequency of the spectrum. The possible oscillations arising in $(\mathcal{H}_Y \cdot \vec{\nabla} \times \mathcal{H}_Y)$ are smeared out as a consequence of the growth of the hyperconductivity which is exactly zero in the inflationary phase but which gets large as soon as the radiation phase is approached.

Without fine-tuning the amplitude of the $\psi$ oscillations we are led to require $\psi_0 \sim M$. If we impose that $n_B/s > 10^{-10}$ we get, from Eq. (6) and in the case of three fermionic generations, the condition

\[
\log_{10} \frac{H_i}{M_P} \gtrsim -8.5 + \log_{10} \left[ \frac{\sigma_0^2}{c^2 N_{eff}} \right] \\
- \frac{2c}{5} m \log_{10} e^{-2} - 2 \log_{10} \frac{m}{H_i},
\]

illustrated in Fig. 1 with the thick (full) line. In order to produce a sizable BAU ($\gtrsim 10^{-10}$ ) we need to be above the thick full line but also below the thin (full) line representing the condition $\omega_m(t) < \omega_a(t)$. Moreover, in order to be consistent with the (undetected) tensor contribution to the Cosmic Microwave Background anisotropy we are led to require $H_i/M_P \lesssim 10^{-6}$. In order to have inflation prior to the onset of the EW epoch we must impose $H_i/M_P > 10^{-33}$. In Fig. 1 this last requirement corresponds to the shaded region within the two dot-dashed lines. Thus, provided $m/H_i \gtrsim 10^4$ the pseudoscalar oscillations produce sufficient helicity to seed the BAU also for reasonably small inflationary scale $H_i \sim 10^{-22} M_P$ (see [4] for further details).

During an inflationary stage $\sigma \rightarrow 0$. If the $\psi$ oscillations take place in a radiation dominated epoch ($\sigma \neq 0$) the evolution of the hypercharge are damped, from the very beginning, thanks to the finite value of the hyperconductivity according to

FIG. 1. With the full thick line we illustrate the bound of Eq. (6) for a fiducial set of parameters ($c = 0.01$, $\sigma_0 \sim 70$ and $N_{eff} = 106.75$). In order to produce a sizable BAU we have to be within the shaded area. The thin line corresponds to the hyperconductivity bound (i.e. $k < k_a$) for Fourier modes amplified during the inflationary epoch and evolving, subsequently, in the radiation phase.
\[
\sigma Y'_\pm + \left[ k^2 + k \epsilon \frac{\psi Y}{M} \right] Y_\pm = 0. \tag{7}
\]

More precisely, for \( T > T_c \), Eq. (6) should be complemented by the equations of anomalous magnetohydrodynamics (AMHD) accounting for the coupled evolution of \( \psi, \mu_R \) (the right electrons chemical potential) and of the velocity field \( \vec{v} \)

\[
\frac{\langle \mu_R a \rangle}{a} = - \frac{g^2}{4 \pi^2} \frac{738 \bar{H}_Y \cdot \nabla \times \bar{H}_Y}{88 \sigma a^3 T^3} - (\Gamma + \Gamma_H) \langle \mu_R a \rangle + D_R \nabla^2 \langle \mu_R a \rangle, \tag{8}
\]

\[
\bar{H}_Y' = \frac{4a}{\pi \sigma} \vec{v} \times \left( \mu_R \bar{H}_Y \right) - \frac{c}{M} \vec{v} \times \left[ \psi \bar{H}_Y \right] + \vec{v} \times \left( \vec{v} \times \bar{H}_Y \right) + \frac{1}{\sigma} \nabla^2 \bar{H}_Y, \tag{9}
\]

\[
\vec{v}' + [\vec{v} \cdot \nabla] \vec{v} = \frac{[\bar{H}_Y \cdot \nabla] \bar{H}_Y}{[\rho + p]} + \nu \nabla^2 \vec{v}, \tag{10}
\]

where \( \alpha(\tau) d\tau = dt \) and \( H = (\ln a)' \). In Eq. (10) we neglected the Lorentz term which is subleading in the case of maximally helical fields and we also used the incompressible closure (i.e. \( \nabla \cdot \vec{v} = 0 \)) of the AMHD equations in the assumption of a perfect fluid with radiation-like equation of state \( p = \rho/3 \). In Eq. (8) on top of the chirality changing rates we introduced the diffusion coefficient of the right electron chemical potential \( D_R \) leading to a typical diffusion scale \( k_0 = \alpha'(T/M_0)^{1/2}/T \). Eqs. (6)–(10) should be generalized to include, in principle, all the processes which are in local thermal equilibrium for \( T > T_c \). However, if we want to focus our attention on the generation of HK right before the EWPT, we are led to consider with special care the right-electrons whose equilibration temperature can fall (in the MSM) in the TeV range. If the thermal and hypermagnetic diffusion coefficients are of the same order (i.e. \( \nu \sim \sigma \)), the solution of Eq. (6) together with Eqs. (8)–(10) determines the evolution of the HK at finite fermionic density. If we insert the result into Eq. (6) we get, in the limit \( k \ll k_\sigma \) and \( k \ll k_D \), that the BAU is given by

\[
\frac{n_B}{s} \approx \frac{45 n_f}{8 \pi^2 \sigma_0} c_{\psi} \left| \frac{T^2}{M_0} \right|, \quad \omega_m = c \frac{\Delta \psi}{2 \alpha M} T^2, \quad \omega_m = \frac{c}{2 \alpha} \frac{\Delta \psi}{M} T^2, \tag{11}
\]

where \( r = |\bar{H}_Y|^2/(N_{eff} T_d^4) \) is the critical fraction of energy density stored in the initial (topologically trivial) hypermagnetic distribution for \( \omega \sim \omega_m \). Notice also that \( \omega_m \) differs, in the present case, from the maximally amplified frequency defined in the context of the inflationary amplification. If we do not fine-tune the initial amplitude of the oscillations to be much larger than \( M \) we have that \( \Delta \psi \sim M \). Concerning Eq. (11) three remarks are in order:

i) it holds provided \( \omega_m < \omega_\sigma \) (indeed only in this limit Eq. (6) is meaningful);

ii) it holds provided we are in the context MSSM since only in this case \( \Gamma \) can be large enough and EWPT can be strongly first order;

iii) it can give a relevant BAU if (and only if) an initial distribution of topologically trivial hypermagnetic fluctuations is postulated, namely \( \rho(\omega_m) \) needs to be at least \( 10^{-3} \), whereas, in the case of vacuum fluctuations \( \rho(\omega_m) \sim N_{eff} (\omega_m/T)^4 \sim 10^{-33} \). This last point implies, physically, that the BAU cannot be generated from vacuum fluctuations of the hypercharge fields. Our observations are not in agreement with [1] where it is assumed that the correct value of the BAU can be reproduced in the MSM, for \( k_m \sim T \) and disregarding the role of the slowest processes in the EW plasma. According to our present analysis we do not share these last statements.

It seems instead more natural, in our scenario, to assume that at the scale where \( \psi \) oscillates in the radiation epoch there is a topologically trivial (stochastic) hypermagnetic distribution since it might have been generated, for example, thanks to the breaking of conformal invariance or through some other mechanism. We focus our attention on temperatures in the TeV range where the right electrons can be still out of thermal equilibrium. Inspired by the axial Higgs we will be concerned with pseudoscalar masses \( m \gtrsim 300 \text{ GeV} \) as required in order to have a MSM Higgs sector not too different from the one of the MSSM.

Comparing the BAU obtained from the previous equation with \( 10^{-10} \) we obtain a condition on the parameters of the model, namely, by imposing \( y \gtrsim -10 \)

\[
-2.4 + \log_{10} c - \log_{10} \sigma_0 + \log_{10} (\frac{\Delta \psi}{M}) + x \gtrsim -10 \tag{12}
\]

where now \( x = \log_{10} r(\omega_m) \) and \( y = \log_{10} (n_B/s) \). This result is illustrated in Fig. 2 for the accessible region of the parameter space in the case \( n_f = 3 \). One could also wonder if the MSM physics would be enough to produce HK. Let us assume, for a moment, the MSM. Then, as argued in [1] and [2], \( \Gamma_H > \Gamma \). Even assuming the EWPT to be strongly first order in the presence of a large hypermagnetic field (which is not the case) from Eq. (6) the
BAU will be given by the expectation value of the highly non-local operator
\[ \frac{\langle \hat{H}_Y \cdot \nabla \times \hat{H}_Y \rangle}{|\hat{H}_Y|^2} \simeq \frac{\langle \hat{H}_Y \cdot \nabla \times \hat{H}_Y \rangle}{|\langle \hat{H}_Y \rangle|^2}, \tag{13} \]
where the last equality can be obtained for sufficiently large scales \( \mathbb{R} \). Then, using Eq. (7) the BAU turns out to be
\[ n_B \simeq 0.04 c \left( \frac{\Delta \Psi}{M} \right) T_R \frac{80 \text{ TeV}}{M_0}, \tag{14} \]
where \( T_R \sim 80 \text{ TeV} \) is the right-electron equilibration temperature \( \mathbb{R} \). For the accessible region of the parameter space the BAU is of the order of \( 10^{-18} \).

Our considerations can have direct phenomenological implications. It is amusing to notice that if a hypermagnetic background is present for \( T > T_c \), then, as discussed in \([16]\) in the context of ordinary MHD, the energy momentum tensor will acquire a small anisotropic component which will source the evolution equation of the tensor fluctuations \( h_{\mu \nu} \) of the metric \( g_{\mu \nu} \):
\[ h''_{\mu \nu} + 2 \nabla h'_{\mu \nu} - \nabla^2 h_{\mu \nu} = -16 \pi G \tau^{(T)}_{ij}. \tag{15} \]
where \( \tau^{(T)}_{ij} \) is the tensor component of the energy-momentum tensor \( \mathbb{R} \) of the hypermagnetic fields. Suppose now, as assumed in \([4]\) that \( |\hat{H}| \) has constant amplitude and that it is also homogeneous. Then as argued in \([2]\) we can easily deduce the critical fraction of energy density present today in relic gravitons of EW origin
\[ \Omega_{gw}(t_0) = \frac{\rho_{gw}}{\rho_c} \simeq z_{eq}^{1/2} \rho_c(T_c) \sim N_{eff} T_c^4, \tag{16} \]
\( z_{eq} = 6000 \) is the redshift from the time of matter-radiation, equality to the present time \( t_0 \). Because of the structure of the AMHD equations, stable hypermagnetic fields will be present not only for \( \omega_{ew} \sim k_{ew} / a \) but for all the range \( \omega_{ew} < \omega < \omega_{\gamma} \). Let us assume, for instance, that \( T_c \sim 100 \text{ GeV} \) and \( N_{eff} = 106.75 \). Then, the (present) values of \( \omega_{ew} \) and \( \omega_{\gamma} \) will be, respectively, \( 2 \times 10^{-5} \) Hz and \( 1.5 \times 10^3 \) Hz. Suppose now, as assumed in \([10]\) that \( |\hat{H}|/T^2 \gtrsim 0.3 \). Thus \( r \simeq 0.1-0.01 \) and \( h_{\gamma}^2 \Omega_{gw} \simeq 10^{-7}-10^{-8} \) which is a respectable signal compatible with (but smaller than) the bounds coming from BBN \([8]\) and implying \( h_{\gamma}^2 \Omega_{gw} \lesssim 10^{-6} \) \([3]\).

The author is deeply indebted to M. Shaposhnikov for very valuable discussions and collaboration.

[19] Notice that the pulsar timing bound (which applies for present frequencies \( \omega_{\gamma} \sim 10^{-8} \) Hz and implies \( h_{\gamma}^2 \Omega_{gw} \lesssim 10^{-8} \)) is automatically satisfied since our hypermagnetic background is defined for \( 10^{-8} \text{Hz} \lesssim \omega \lesssim 10^3 \text{Hz} \).
