Change in Physical Activity During a Weight Management Intervention for Breast Cancer Survivors: Association with Weight Outcomes

Tera L. Fazzino 1, Carol Fabian 2, and Christie A. Befort 1

Objective: This study examined the effects of a group phone-based weight management intervention on change in physical activity as measured via accelerometer and self-report in rural breast cancer survivors. The study also evaluated the role of physical activity on clinically meaningful cut points for weight loss (baseline to 6 months) and weight loss maintenance (6 to 18 months).

Methods: Participants were breast cancer survivors in a weight management intervention who provided valid weight and accelerometer data ($N = 142$). Participants were categorized into four groups based on weight loss ≥10% and weight regain ≥5% at 18 months.

Results: Accelerometer-measured moderate-to-vigorous physical activity (MVPA) significantly increased from baseline to 6 months (+46.9 minutes). MVPA declined during maintenance but remained significantly greater than baseline. Self-reported MVPA followed a similar pattern as accelerometer MVPA, but estimates were significantly higher. Participants in the high loss, low regain group had significantly higher MVPA at all points.

Conclusions: A distance-based weight management intervention for survivors improved physical activity outcomes over 18 months. Self-reported physical activity was substantially higher than accelerometer measured. Findings highlight the importance of device-based measurement for characterizing the magnitude of physical activity change as well as the role of physical activity in weight management outcomes.

Obesity (2017) 25, S109–S115. doi:10.1002/oby.22007

Introduction

Obesity and physical activity are modifiable risk factors for breast cancer and cancer recurrence (1,2). Physical activity may reduce breast cancer risk directly through its effects on chronic inflammation and sex hormones, as well as indirectly through its effects on obesity-related factors such as adiposity, insulin resistance, and adipokines (3,4). During weight loss, moderate-to-vigorous physical activity (MVPA) helps induce caloric expenditure to reach a prescribed caloric deficit needed for weight loss. A systematic review of weight loss studies targeting both diet and physical activity changes over 3 to 12 months reported a small, positive additive effect of physical activity during weight loss (pooled estimate = $-1.65$ kg) (5). Whereas physical activity may have a smaller role in weight loss, physical activity is crucial for successful long-term weight loss maintenance (6,7). The American College of Sports Medicine recommends 200 to 300 MVPA min/wk for sustained weight loss maintenance (8). In this regard, Jakicic (2014) examined weight loss maintenance patterns among participants from the general population and found that those who sustained ≥10% weight loss at 6 and 18 months were more likely to complete 200 + minutes of MVPA per week (7).

Comprehensive clinical weight management trials tailored to breast cancer survivors that targeted reduced caloric intake, increased energy expenditure, and behavioral strategies have yielded initial evidence of physical activity improvements during initial (up to 6 months) and more long-term (up to 18-24 months) intervention periods (9). The Exercise and Nutrition to Enhance Recovery and Good Health for You (ENERGY) trial included a home-based (nonsupervised) physical activity component (10). During weight loss (0 to 6 months), self-reported MVPA min/wk increased 150% in the intervention group (94 to 238 min/wk) and increased by 50% in the non-intervention control group (103 to 163 min/wk) (10). Similar improvements were found in 18-month outcomes of the LISA
weight loss trial (11). Participants randomized to the phone-based intervention had self-reported improvements from 0 to 18 months (110% increase: 120 to 250 min/wk), as did participants in the mail-based intervention (122% increase: 95 to 210 min/wk) (11).

Measuring physical activity using self-report is common in lifestyle interventions for breast cancer survivors; it affords low participant burden and can be highly scalable to large trials. However, measuring physical activity using self-report questionnaires can overestimate physical activity as compared to device-based measurement with accelerometers (12,13), possibly because these measures assess different aspects of physical activity or different constructs (13). For example, self-reported physical activity participation may also reflect an individual’s perceived ease or difficulty in physical activity participation (13). To our knowledge, only two pilot weight loss trials among breast cancer survivors have reported findings on physical activity change using device-based measurement. One single-arm pilot study designed to provide extended care for weight loss maintenance via text messages indicated that accelerometer-measured MVPA significantly increased from baseline to 18 months; however, the magnitude of the increase was lower (38% increase) than the aforementioned self-reported physical activity increases in other breast cancer trials (14). In the Lifestyle, Exercise, and Nutrition (LEAN) randomized pilot study, pedometer steps increased by 37% in the in-person treatment group and 16% in the telephone treatment group from baseline to 6 months (15). Importantly, participants in both LEAN treatment groups self-reported a higher increase in MVPA min/wk (86%-115%). Thus, self-report of physical activity may overestimate treatment effects on physical activity among breast cancer survivors. This has important implications for addressing unanswered questions about the relative importance of weight loss versus physical activity change in prognostic factors for recurrence and survival. However, given that pedometer-measured physical activity can yield substantial measurement error (16) and no self-report measures were reported for comparison in the accelerometer study, it is difficult to determine the degree to which self-report may overestimate physical activity in treatment samples of breast cancer survivors.

The goals of the current study were threefold. The first aim was to examine the effects of an 18-month group phone-based weight loss intervention for rural breast cancer survivors on change in physical activity from 0 to 6 months (weight loss phase) and from 6 to 18 months (weight loss maintenance phase). Our second aim was to compare estimates of physical activity change across accelerometer versus self-report measures. The third aim was to compare physical activity changes across weight loss and weight regain groups as defined by clinically meaningful cut points.

Methods
Study design
This study was designed to compare continued group phone-based counseling versus mailed newsletters on weight loss maintenance following weight loss. Study details and primary outcomes were presented previously (17,18) and are briefly described herein. Participants (N = 210) were postmenopausal female breast cancer survivors residing in rural areas of the Midwestern United States, with a BMI of 27 to 45 kg/m², age <75 years, diagnosis of Stage 0-IIIC disease, and completion of breast cancer treatment. The intervention consisted of (1) a 6-month weight loss phase during which all participants received weekly group phone sessions, followed by (2) a 12-month weight loss maintenance phase (6 to 18 months) during which participants were randomized to continued phone sessions or a newsletter condition. Participants in the phone group received biweekly phone sessions, whereas newsletter condition participants received mailed newsletters at the same frequency as the phone sessions that covered the same content as the group calls.

The primary end point for the main trial was weight regain from 6 to 18 months among participants who lost ≥5% by 6 months. However, all participants continued in the intervention and were followed throughout the study and are reported here. The study was approved by the university’s Institutional Review Board, and informed consent was obtained from all participants.

Study sample
The sample for the current analyses consisted of participants who provided valid weight and accelerometer data at baseline and at 6 and 18 months. Figure 1 depicts how we obtained our final sample of N = 142.

Intervention
During the 6-month weight loss phase, participants met via conference call for 1 hour weekly. Participants were instructed to follow a structured meal plan and to gradually increase their physical activity, with the goal of 225 min/wk of MVPA by week 12, consistent with...
recommendations (8). Participants received a Physical Activity Tool Kit with two DVDs, a pedometer, and self-monitoring charts. Brisk walking was the activity of choice for most participants. Physical activity sessions addressed both education to ensure safety, monitor and regulate intensity, and increase exercise variety, as well as problem-solving activities to address common barriers, including issues regarding the built environment in rural settings (lack of sidewalks, extreme temperatures, etc.), sustaining motivation, and social support. Participants submitted a weekly self-monitoring report form detailing their dietary intake, physical activity minutes at ≥10-minute bouts, and steps per day (goal of 10,000/day). During each session, participants reported whether they met nutrition and physical activity goals from the previous session.

Assessments

Participants attended assessment visits at baseline and at 6, 12, and 18 months. At each visit, participants were weighed in light clothing (shorts, t-shirt) in a fasting state using a calibrated digital scale accurate to 0.1 kg (Befour PS5700). Height was measured with a stadiometer.

Both self-report and accelerometer measures of physical activity were collected at all time points. Participants were instructed to wear a GT3X + ActiGraph Accelerometer (ActiGraph, Fort Walton Beach, Florida) for 7 consecutive days at each point. The ActiGraph has been shown to provide valid assessments of activity intensity during both walking/running (19) and daily living activities (20). The device does not have a display screen to minimize reactivity. Participants received verbal and written instructions accompanied by a wear time log to help encourage adherence. Devices were returned in a pre-stamped envelope. Participants’ data were included if data was available for ≥10 h/d for ≥4 days, an algorithm that has been demonstrated to validly estimate physical activity patterns (21). The accelerometer outcome variable was a total of ≥10-minute MVPA bouted minutes per week, consistent with the intervention guidelines for counting only ≥10-minute bouts toward total weekly minutes. Prior studies have found this measure to be more predictive of weight loss outcomes than non-bouted minutes (7). Data in counts per minute summed across 10-second epochs were downloaded, and number of minutes per day at various activity levels were calculated using the cut points suggested by Matthews et al. (22). MVPA (counts ≥1,952 per minute) bouts wherein at least 8 minutes were at or above the 1,952 threshold were used to identify 10-minute MVPA bouts. Bouted MVPA minutes per valid day (≥10 hours worn) were calculated and multiplied by 7 to obtain weekly estimates.

The Paffenbarger Physical Activity Questionnaire (23) includes questions on stairs climbed, blocks walked, and other sports, leisure, and recreational activities on a typical week during the past month. All activities were assigned metabolic equivalent values (24), and MVPA minutes (metabolic equivalent values >3) were summed to obtain weekly MVPA min/wk estimates. Total MVPA min/wk was used as the self-report outcome variable to allow for direct comparison to the accelerometer measure. Self-report physical activity measures were available for 139 of the 142 participants in the sample (98%). Two participants at 6 months and one at 18 months had self-report measures that were statistical outliers and were physically implausible.

Weight-change groupings

We classified participants into low/high weight loss (<10% loss vs. ≥10% loss from baseline to 6 months) and further into low/high weight regain (<5% regain vs. ≥5% regain from 6 to 18 months). This resulted in four weight-change groups.

Analyses

We first calculated descriptive statistics for the outcome measures, as well as the percentage of participants who met physical activity guidelines of ≥150 min/wk. Both outcomes were square-root transformed to correct for skewness. We examined the effects of randomization condition at 6 months on MVPA change during maintenance (6-18 months) using a linear mixed model. There were no significant differences in MVPA change between the conditions; therefore, the groups were combined for the main analyses.

Separate repeated-measures analyses of variance (ANOVAs) were run to examine changes in accelerometer and self-reported physical activity during the weight loss phase (baseline to 6 months) across the full sample, as well as the four weight-change groups. A Bonferroni adjustment was used for multiple comparisons between groups. A series of paired t tests were used to test for significant differences between accelerometer-measured and self-reported MVPA at each time point. Separate linear mixed models using a compound symmetry correlation structure were constructed to examine changes in accelerometer and self-reported MVPA outcomes across the three time points during the weight loss maintenance phase (6, 12, and 18 months) for the full sample, as well as the weight-change groups. Finally, an interaction between time and weight-change group was included to examine differences between groups by time point, using a Bonferroni adjustment. We included the following variables as covariates in the models: randomization assignment, age, education, rurality (large rural vs. small/isolated rural (25)), and time since end of cancer treatment. We used restricted maximum likelihood estimation to cope with missing data.

Results

Table 1 presents participant characteristics. Participants were a mean of 58.6 (SD = 8.0) years old, 76% were married, and 22% had a 4-year college degree. Participants were a mean of 3.6 (SD = 2.5) years beyond cancer treatment, excluding antihormone therapy. Mean baseline BMI was 33.7 (4.0). Weight loss at 6 months was 13.9% (SD = 5.74), and participants regained a mean of 4.6% (SD = 5.9) by 18 months.

Participants in the current sample did not significantly differ on age, baseline BMI, or cancer treatment-related variables (all P > 0.05) from those who attended the 6-month visit but were excluded from the current analyses based on missing or invalid accelerometer data. Additionally, participants in the current sample did have significantly higher percent weight loss at 6 months (13.9% vs. 10.1%, P = 0.001) than those who attended the 6-month visit but were excluded from the current analyses based on missing or invalid accelerometer data. However, these participants did not significantly differ in percent weight regain from 6 to 18 months (4.6% vs. 6.4%, P = 0.083).
TABLE 1 Demographic characteristics (N = 142)  

| Variable                        | Mean (SD) or n (%) |

Change in physical activity
Table 2 shows within-subject changes in MVPA over 18 months. Accelerometer-measured median MVPA bouted minutes significantly increased from baseline to 6 months (18.4 vs. 65.3, P = 0.001; an increase of 350% from baseline, and significantly decreased from 6 to 18 months (65.3 vs. 38.1, P = 0.01; a 42% decrease from 6 months). MVPA at 18 months remained significantly higher than baseline (18.4 vs. 38.1, P = 0.001; a 210% increase).

Within the weight-change groups, accelerometer MVPA significantly increased from baseline to 6 months among both high weight loss groups but not the low loss groups. In addition, accelerometer MVPA significantly decreased from 6 to 18 months in the high loss groups but not in the low loss groups.

Self-reported MVPA min/wk significantly increased in the full sample (0 vs. 227.5, P = 0.001; a 227% increase) as well as in all weight-change groups ( Ps < 0.001) from baseline to 6 months. From 6 to 18 months, self-reported MVPA min/wk significantly decreased in the full sample (227.5 vs. 150.0; a 34% decrease), as well as in all groups except the low loss, high regain group (Table 2). Self-reported MVPA min/wk at 18 months were 150% higher than baseline.

Table 3 shows the percentage of participants in each weight-change group that met MVPA guidelines. Accelerometer data indicated <15% of participants in both low loss groups met MVPA guidelines of ≥150 min/wk at any time point. In contrast, 30% to 43% of participants in the high loss groups met ≥150 min/wk guidelines at 6 months. In the high loss, low regain group, 25% met guidelines at 12 months, which increased to 32% at 18 months.

By self-report, over 60% of participants in all weight-change groups reported meeting ≥150 min/wk at 6 months. At 12 and 18 months, 26% to 39% of participants in the low loss groups reported meeting guidelines compared to 47% to 75% in the high loss groups.

Accelerometer vs. self-reported MVPA
Self-reported MVPA was significantly higher than accelerometer-measured MVPA at 6 months (P = 0.001) and 18 months (P = 0.001) in the full sample. Findings were similar among all four weight-change groups (Table 2).

Physical activity across weight-change groups
Group comparisons for accelerometer-measured MVPA over time are depicted in Figure 2. There were no baseline group differences in MVPA. There was a significant interaction between group and time (P = 0.031). At 6 months, median MVPA in both of the high loss groups was significantly higher compared to the low loss groups (Ps < 0.05). At 12 and 18 months, the high loss, low regain group had significantly higher MVPA than all other groups. Notably, the high loss, low regain group’s MVPA decreased at 12 months but stabilized by 18 months, while the high loss, high regain group’s MVPA decreased at 12 months and 18 months.

Discussion
The present study demonstrated that a distance-based weight management intervention for breast cancer survivors that targeted home-based physical activity improved physical activity outcomes over 18 months. Specifically, MVPA assessed via accelerometer significantly increased (+46.9 minutes) from baseline to 6 months in the full sample. MVPA bouted minutes did decline during weight loss maintenance (6-18 months); however, MVPA at 18 months was still significantly greater than baseline, suggesting some maintenance of effects. Our observed changes in MVPA (median = 46.9 minutes) are consistent with the increases in MVPA min/wk observed in The Weight Loss Maintenance Randomized Controlled Trial in the general population (mean = 48 minutes at 6 months) (26). Compared to previous weight loss intervention trials in breast cancer survivors, self-reported physical activity changes from baseline to 18 months among our participants (150%) were similar in magnitude to the LISA phone-intervention condition (110%: 120 to 250 min/wk) (11) and higher than those of the ENERGY trial (79%, 94 to 168 min/wk). Participants in our study had lower physical activity at baseline compared to these other trials, a finding that may reflect environmental, cultural, and access-related barriers to physical activity in rural settings (27,28).

Only a minority of our participants achieved a level of physical activity consistent with guidelines, and there were no substantial differences between the phone- and mail-based maintenance interventions during the maintenance phase. Novel strategies are needed to improve adherence to physical activity recommendations in
Our findings suggest maintenance of effects is possible in this population and warrants further attention.

Our findings add to the preliminary evidence indicating self-reported physical activity can be substantially inflated as compared to device-based measurement among breast cancer survivors (12,14,15). The discrepancy between self-report and accelerometer measures in the current study was striking; median self-reported MVPA at 6 and 18 months was more than triple accelerometer-measured MVPA. Self-report estimates were particularly inflated in the low loss groups at 6 months and in all groups except the high loss, low regain group at 18 months, indicating bias in self-reported physical activity may be triple accelerometer-measured MVPA. Self-report estimates were particularly inflated in the low loss groups at 6 months and in all groups except the high loss, low regain group at 18 months, indicating bias in self-reported physical activity may be substantially inflated as compared to device-based measurement among breast cancer survivors (12,14,15).

The study had several limitations. First, our analyses were limited to participants who provided valid accelerometer wear time, and this participant group had higher weight loss compared to those without valid accelerometer data. If we had obtained data from the excluded participants, our estimates of physical activity during the program may have been lower overall. However, the percentage of participants with valid accelerometer wear time was considerably lower than with self-report data (70 versus 50, respectively). This could result in much higher values for self-report estimates, which may have been inflated to a degree that masks true discrepancies.

Our findings are consistent with those of Jakicic et al. (2014), who reported a similar pattern of MVPA stabilization at 12 and 18 months among participants from the general population who successfully maintained 10% weight loss at 18 months (7). Taken together, these findings highlight the importance of preventing or minimizing the decline in physical activity during maintenance. A stepped care approach focused on sustaining or further increasing MVPA during maintenance may have benefits for preventing weight regain long-term. Given that motivation and engagement tend to decline during maintenance, a shift in intervention focus from primarily maintaining compliance with weight management skills learned during weight loss to expanding participants’ physical activity goals and participation (physical activity type, duration, and frequency) may provide novelty and variety that could better sustain physical activity and may improve weight management outcomes.

| High loss, low regain       | 25 (13)         | 90 (47)         | 65 (34)          | 75 (39)          |
| High loss, high regain      | 23 (11)         | 76 (35)         | 47 (21)          | 48 (22)          |

Low loss, low regain: <10% loss at 6 months, <5% regain at 18 months.
Low loss, high regain: <10% loss at 6 months, ≥5% regain at 18 months.
High loss, low regain: ≥10% loss at 6 months, <5% regain at 18 months.
High loss, high regain: ≥10% loss at 6 months, ≥5% regain at 18 months.

The major strength of the study is the use of both accelerometer and self-reported measures of physical activity in addition to the broad range of high and low weight loss and regain groups, which allowed for comparisons across the four corresponding subgroups.

Conclusion

A phone-based weight management intervention for breast cancer survivors that targeted nonsupervised physical activity improved MVPA min/wk at 6 months, with partial maintenance of effects at 18 months. However, the majority of participants did not meet guideline thresholds, pointing to the continued need for enhancing intervention effects on physical activity. Self-reported physical activity changes were more than triple those of the accelerometer-measured changes, suggesting that measurement is crucial for accurately specifying the magnitude of physical activity changes during a weight management intervention. The highest levels of sustained physical activity were important for clinically significant weight loss as well as successful weight loss maintenance by 18 months.
