(Received 14 July 2017; revised manuscript received 17 November 2017; published 5 December 2017)

We give a self-contained derivation of the low-energy effective interactions of the SU($N$) Hubbard model, a multiflavor generalization of the one-band Hubbard model, by using a generalized Schrieffer-Wolff transformation (SWT). The effective interaction of doublons and holons, which has been largely ignored in previous SWT studies (e.g., the $t$-$J$ model), leads to distinct peaks in the local density of states. As shown by Lee et al. [Phys. Rev. Lett. 119, 236402 (2017)], this underlying effective doublon-holon interaction explains the numerical observation of the subpeaks at the inner edges of the Hubbard bands in the metallic phase close to the Mott transition.

DOI: 10.1103/PhysRevB.96.245106

I. INTRODUCTION

The Schrieffer-Wolff transformation (SWT) [1] was introduced in the 1960s to derive the Kondo model as an effective low-energy Hamiltonian for the single-impurity Anderson model. Since then, variations and generalizations of its basic idea have been used in numerous contexts in condensed matter physics, to map many-body Hamiltonians onto simpler effective Hamiltonians describing the effective degrees of freedom accessible at low excitation energies.

One paradigmatic application concerns the one-band Hubbard model [2]. From the nearest-neighbor particle hopping and the on-site Coulomb interaction in the Hubbard model, the SWT yields, up to leading order, several different types of effective interactions: an exchange interaction between nearest-neighbor spins, an interaction between doublon and holon on nearest neighbors, and three-site terms involving next-nearest neighbors. Here we define doublon (holon) as the local excitation having one more (less) particle than the average occupation number, which naturally generalizes to the multiflavor case discussed below.

When the $t$-$J$ model [2], an effective description of doped Mott insulators, is derived from the Hubbard model, the effective interactions are projected onto charge sectors which select a specific integer filling, and one allows charge fluctuations into either the doublon or the holon sector, but not both. This inequivalent treatment for doublon and holon is appropriate for the description of doped Mott insulators in which doublon and holon hardly coexist, since the excitation energy of doublon (holon) is much higher than that of holon (doublon) in the hole-doped (particle-doped) case [3]. Thus the doublon-holon interaction drops out, and three-site terms are neglected as an additional approximation. As a result, only the exchange interaction, among all the effective interactions mentioned above, survives, yielding the $t$-$J$ model.

Unlike the exchange interaction, which is at the heart of quantum magnetism, the role of the doublon-holon interaction has not received much attention so far. However, the doublon-holon and exchange interactions have strengths comparable in magnitude. Therefore one may suspect that the doublon-holon interaction can lead to measurable phenomena of its own, especially when the coexistence of doublon and holon is substantial.

In a related paper [4], we have identified a situation where this is indeed the case: The doublon-holon interaction is responsible for previously unexplained subpeaks at the inner edges of the Hubbard bands of the local spectral function, i.e., the local density of states. Many dynamical mean-field theory (DMFT) studies [5–11] have observed that such subpeaks emerge in the metallic phase close to the Mott transition. Though the other spectral features in the spectral function, i.e., the quasiparticle peak and the Hubbard bands, are well understood, the physical origin of the subpeaks had remained unknown. In Ref. [4] we have proposed an explanation for their origin: They arise from doublon-holon correlations. To demonstrate this, we numerically computed the correlation functions of doublons and holons, finding peak structures that indeed correlate with those of the subpeaks in the local density of states. Moreover, we also argued that the generic features of these subpeaks can be understood by using an effective low-energy model derived by a generalized SWT, and treated by a mean-field decoupling scheme.

In this work, we provide a concise self-contained derivation of the generalized SWT employed in Ref. [4]. First, we derive the low-energy effective Hamiltonian of the SU($N$) Hubbard models by employing a generalized Schrieffer-Wolff transformation (SWT) [12,13] inspired by a high-frequency expansion [14] in the Floquet theory. Then we study the correlation functions of doublons and holons, focusing on the intermediate energy scale which lies between the larger energy scale associated with the Hubbard bands and the smaller scale with the quasiparticle peak. By adopting a mean-field decoupling scheme, we briefly analyze the peak structure in the local spectral functions related to the doublon-holon dynamics. Finally, we argue that the peak structure becomes more pronounced with increasing number $N$ of particle flavors, since the doublon-holon interaction acts on larger Hilbert space. This is consistent with DMFT results from Ref. [4].

II. LOW-ENERGY HAMILTONIAN

A. Generalized SWT

We consider the SU($N$) Hubbard model, which is the simplest multiflavor generalization of the one-band Hubbard
model for $N = 2$ spinful flavors. The Hamiltonian for the SU($N$) Hubbard model,  
\begin{equation}
H = \frac{U}{2} \sum_{i} \left( \langle \hat{n}_i - \bar{n} \rangle^2 - \mu \right) \hat{n}_i + \sum_{i,j,v} v_{ij} c_{i,j,v}^\dagger c_{j,v},
\end{equation}
describes $N$ symmetric flavors of fermions on a lattice, with Coulomb interaction strength $U$, chemical potential $\mu$, and hopping amplitude $v$. Consequently, the Hamiltonian has SU($N$) flavor symmetry. In this paper, we focus on the cases in which the average occupation is integer, i.e., $\langle \hat{n}_i \rangle = \bar{n} \in \mathbb{N}_0$. In Eq. (1), $c_{ij}$ annihilates a particle of flavor $v = 1, \ldots, N$ at site $i$. The Coulomb interaction $H_U$ yields finite energy when the particle number $\hat{n}_i \equiv \sum_v c_{i,j,v}^\dagger c_{i,j,v}$ at each site $i$ deviates from $\bar{n}$. By preferring finite occupation $\bar{n}$, this term contains a significant portion of the chemical potential. With $\frac{1}{2} (\bar{n}_i - \bar{n})^2 = \frac{1}{2} \bar{n} (\bar{n}_i - 1) + U (\bar{n} - \bar{n}_i) + \text{const.}$, the first term on the right-hand side is the “bare” Coulomb interaction, whereas the second term represents an offset $U (\bar{n} - \frac{1}{2})$ to the chemical potential.

The term $H_U$ describes an additional fine tuning of the chemical potential to ensure $\langle \hat{n}_i \rangle = \bar{n}$. For example, particle-hole symmetry is given by $\bar{n} = N/2$ and $\mu = 0$, resulting in half filling ($\langle \hat{n}_i \rangle = N/2$). Otherwise for $\langle \hat{n}_i \rangle = \bar{n} \neq N/2$, one typically has $\mu \neq 0$. Since, by construction, the term $H_U$ contains the largest contribution to the total chemical potential, we typically have $|\mu| \ll U$.

Finally, the kinetic term $H_v$ represents a hopping between nearest neighbors with real hopping amplitude $v$, by defining $v_{ij} = v_{ji} = v$ when sites $i$ and $j$ are nearest neighbors and $v_{ij} = 0$, otherwise.

1. Projected operators

The first step of the generalized SWT is to identify the dominant high-energy term to be integrated out. In Eq. (1), this is the Coulomb interaction term $H_U$ at energy scale $U$. Given that the Coulomb interaction is solely sensitive to the local occupation number of a specific site, it will be important to meticulously keep track of the local site occupation when considering individual hopping events as part of the kinetic energy term in the Hamiltonian.

This requires one to introduce the projectors $P_{i,n}$ onto the subspace where a site $i$ has $n$ particles, with the completeness relation,
\begin{equation}
\sum_{n=0}^{N} P_{i,n} = 1.
\end{equation}
Then we can decompose a particle operator $c_{i,v}^\dagger$,
\begin{equation}
c_{i,v}^\dagger = \sum_{n=1}^{N} P_{i,n} c_{i,v}^\dagger \equiv \sum_{n=0}^{N} c_{i,v,n}^\dagger,
\end{equation}

Here, by definition, $\tilde{c}_{i,v,n}^\dagger$ creates a particle at site $i$ leading to a final occupation of $n$ particles. Conversely, $\tilde{c}_{i,v,n}$ destroys a particle starting from an initial site occupation of $n$ particles. Note that $\tilde{c}_{i,v,n}^\dagger = c_{i,v} P_{i,n} = P_{i,n-1} c_{i,v}$ are projected operators (also called Hubbard operators), and hence no longer satisfy canonical fermionic anticommutation relations. We will use the tilde as a reminder of this fact throughout. As already indicated on the right-hand side of Eq. (3), the range of $n$ is $[1, N]$ unless specified otherwise.

For sufficiently large $U$, large charge fluctuations $|n_i - \bar{n}| > 1$ will be suppressed in low-energy subspace due to large Coulomb energy cost. (Here $n_i$ stands for the eigenvalue of an operator $\hat{n}_i$.) So we distinguish doublon and holon operators,
\begin{equation}
d_{i,v}^{1} \equiv c_{i,v,n+1}, \quad h_{i,v}^{1} \equiv \tilde{c}_{i,v,n},
\end{equation}

from the other projected operators $\tilde{c}_{i,v,n}$. They describe the more relevant excitations in low-energy subspace. In the following derivation, however, we will consider all possible contributions to the effective Hamiltonian in an unbiased way. Whether each contribution is relevant or not will be determined by the nature of the phase we study, after all possible contributions are collected first; see Sec. II C for more details.

2. Rotating frame

In a second step, the generalized SWT considers a rotating frame whose time evolution is generated by the term $H_U$ with the largest energy scale $U$. A state $|\psi(t)\rangle$ in the laboratory frame is transformed to $|\psi_{\text{rot}}(t)\rangle = e^{iH_U t} |\psi(t)\rangle$ in the rotating frame. This state evolves in time via the Schrödinger equation $i \frac{d}{dt} |\psi_{\text{rot}}(t)\rangle = H_{\text{rot}}(t) |\psi_{\text{rot}}(t)\rangle$ in which the rotating frame Hamiltonian $H_{\text{rot}}$ is related to the laboratory frame as
\begin{equation}
H_{\text{rot}} = -H_U + e^{iH_U t} H e^{-iH_U t}.
\end{equation}

Evaluating the term $e^{iH_U t} H e^{-iH_U t}$, the structure of the Baker-Campbell-Hausdorff formula, $e^X e^Y = e^{X + [X, Y] + \frac{1}{2}[X, [X, Y]] + \frac{1}{6}[X, [X, [X, Y]]] + \cdots}$, suggests that it is convenient to decompose the hopping term as
\begin{equation}
H_v = \sum_{i,j,v} v_{ij} c_{i,j,v}^\dagger c_{j,v} (3) \sum_{n,n' i,j,v} v_{ij} \tilde{c}_{i,v,n}^\dagger \tilde{c}_{j,v,n'},
\end{equation}
where the constrained hopping terms $H_{\text{v,,n'}}$ only include hopping between sites with fixed initial occupations. Then the corresponding energy cost for this hopping process is described by the special structure of the commutator,
\begin{equation}
[H_U, H_{\text{v,,n'}}] = (n - n') U \cdot H_{\text{v,,n'}},
\end{equation}

where, importantly, $H_{\text{v,,n'}}$ again occurs intact on the right-hand side. The prefactor $(n - n') U$ on the right-hand side is the cost of Coulomb energy to arrive at the final charge configuration after acting with $H_{\text{v,,n'}}$ on the initial charge configuration. Consider then, e.g., the hopping process $\tilde{c}_{i,v,n}^\dagger \tilde{c}_{j,v,n'}$ in $H_{\text{v,,n'}}$ from site $j$ to site $i$. If $n = n'$, there is no cost of Coulomb interaction to be paid since initial and final charge configurations are the same yet swapped, i.e., the charge configuration changes from $(n_i, n_j) = (n - 1, n)$ to $(n, n - 1)$. Conversely, for $n > n'$, the charge imbalance $n_i - n_j > 0$ between sites $i$ and $j$ further increases by acting with $H_{\text{v,,n'}}$. Therefore the Coulomb energy to be paid, $(n - n') U > 0$, is positive.

Due to the specific structure of the Coulomb interaction in the Hubbard model, the prefactor on the right-hand side
of Eq. (7) only depends on the difference \( n - n' \). Hence we can further group the terms \( H_{v;m,n'} \) with the same \( m \equiv n - n' \), resulting in

\[
H_v = \sum_{m=-(N-1)}^{N-1} \sum_{n=1}^{N} \frac{H_{v;n,m}}{mU} ,
\]

(8a)

where

\[
[H_v, H_{v;n,m}] = mU \cdot H_{v;n,m} ,
\]

(8b)

\[
H_{v;c} = H_{v;n,m} .
\]

(8c)

The index range \(-N < m < N\) will be implied unless specified otherwise.

Now substituting Eq. (8b) into Eq. (5), we obtain the rotating frame Hamiltonian,

\[
H_{\text{rot}} = H_{\mu} + \sum_{m} H_{v;n,m} e^{i m U t} .
\]

(9)

This is periodic in time with the driving frequencies given by harmonics of the Coulomb interaction \( U \).

3. Effective Hamiltonian

The last step of the generalized SWT is to average out fast dynamics at frequency scale \( \gtrsim U \) within the rotating frame Hamiltonian \( H_{\text{rot}} \). Thus one obtains an effective Hamiltonian \( H_{\text{eff}} \) that describes slow, i.e., nonstroboscopic dynamics. This \( H_{\text{eff}} \) is derived by applying the high-frequency expansion to \( H_{\text{rot}} \) [12, 13]. (In contrast, an effective Hamiltonian given by the Magnus expansion generates the dynamics exactly stroboscopically, e.g., multiples of \( 2\pi/U \) [13].) Then we expand the Hamiltonian as a power series in the inverse frequency \( 1/U \), with the result,

\[
H_{\text{eff}} = H_{\mu} + H_{v;0} + H_{v;U} + O(v^3/U^2) ,
\]

\[
H_{\text{eff}} = \sum_{m \neq 0} H_{v;n,m} e^{i m U t} .
\]

(10)

Essentially, the newly generated term \( H_{v;U} \) resembles second-order perturbation theory in \( v/U \), yet with subtle twists (see discussion in Sec. II C). Via the commutator structure in Eq. (10), only those terms in \( H_{v;U} \) survive the lattice sums in \( H_{v;n,m} \) and \( H_{v;U} \), for which the pairwise nearest-neighbor hoppings overlap with respect to the sites they act upon. Hereafter we will neglect the term of order \( O(v^3/U^2) \).

The nonstroboscopic time evolution of operators \( \tilde{c}_{\nu;m} \) in the original laboratory frame is equivalent to the evolution, generated by \( H_{\text{eff}} \), of the dressed operators \( \tilde{c}_{\nu;m} \) which are obtained by averaging out the fast motion of \( \tilde{c}_{\nu;m} \) [12, 13].

We find that \( \tilde{c}_{\nu;m} = \tilde{c}_{\nu;m} + O(v^2/U^2) \), i.e., the correction to \( \tilde{c}_{\nu;m} \) has the same order as the term in \( H_{\text{eff}} \) to be neglected. Hence we can consistently neglect both high-order terms, i.e., \( H_{\text{eff}} \approx H_{\mu} + H_{v;0} + H_{v;U} \) and \( \tilde{c}_{\nu;m} \approx \tilde{c}_{\nu;m} \), to describe the original nonstroboscopic dynamics of \( \tilde{c}_{\nu;m} \) up to order \( O(v^3/U^2) \).

4. Pair hopping and symmetry

The effective low-energy Hamiltonian \( H_{\text{eff}} \) cannot break the symmetries present in the original Hamiltonian \( H \). Here for the SU(\( N \)) Hubbard model, these are \( U(1)_{\text{charge}} \) symmetry and \( SU(N)_{\text{flavor}} \) symmetry for general \( N \). All parts that constitute \( H_{\text{eff}} \), therefore, also must respect these symmetries.

The elementary building block in \( H_v \) in Eq. (6), is the dimensionless operator,

\[
\Pi_{ij;m} = \frac{v_{ij}}{U} \sum_{\nu} c_{\nu,i}^\dagger c_{\nu,j} ,
\]

(11)

which encodes the phase of the hopping amplitude \( v_{ij} \) (with \( v \) taken real and positive), as well as the nearest-neighbor lattice structure of the Hamiltonian. Due to the operator \( \Pi_{ij;m} \) constitutes the kinetic energy \( H_v \) in Eq. (8a), and thus subsequently also the effective interaction \( H_{v;U} \) in Eq. (10). \( \Pi_{ij;m} \) preserves the \( U(1)_{\text{charge}} \otimes SU(N)_{\text{flavor}} \) symmetry, and therefore represents a scalar operator with respect to these symmetries. Nevertheless, it is a non-Hermitian operator in that it describes the directed and projected hopping process from site \( i \) to site \( j \).

For the projected hopping \( \Pi_{ij;m} \) in Eq. (12), the case \( m = 1 \) is special in that the state on which \( \Pi_{ij;m} \) acts must have a component with equal occupation \( n - \bar{n} \) on both sites, and \( i \) and \( j \). This operator can be symmetrized with respect to the lattice sites,

\[
\Pi_{ij;S}^{\bar{n} + 1} = \frac{1}{2} (\Pi_{ij;S}^{\bar{n}} + \Pi_{ji;S}^{\bar{n}}) \]

(13a)

\[
= \frac{1}{2} \sum_{\nu} (c_{\nu,i}^\dagger c_{\nu,j} + c_{\nu,j}^\dagger c_{\nu,i}) \cdot P_{\nu,n-1} P_{\nu,n-1} ,
\]

(13b)

where in the last line \( \bar{n} = n - 1 \) represents the average integer filling. Now when acting on an initial state \( |\psi\rangle \), the operator \( \Pi_{ij;S}^{\bar{n} + 1} \) first projects into the charge sector of \( \bar{n} \) particles on both sites \( i \) and \( j \), i.e., \( |\psi\rangle \equiv P_{\nu,n-1} P_{\nu,n-1} |\psi\rangle \) and then generates a nearest-neighbor particle-hole excitation, i.e., a doublon-holon pair, by transferring one particle from site \( j \) to site \( i \) or vice versa. Note that \( \Pi_{ij;S}^{\bar{n} + 1} \) is still non-Hermitian.

For the case \( \bar{n} = 2 \) with particle-hole symmetry, the symmetrized operator \( \Pi_{ij;S}^{\bar{n}} \) [i.e., having \( \bar{n} = 1 \) in Eq. (13b)] generates a singlet in the particle-hole sector, and thus respects larger symmetry: the \( SU(2)_{\text{charge}} \) symmetry. For a single site, half-filled states are singlets with respect to the \( SU(2)_{\text{charge}} \) symmetry, i.e., have charge quantum number \( C = 0 \), whereas doublon and holon states represent a doublet with \( C = 1/2 \) [15]. Taking the half-filled case for two sites then, using standard spin notation, i.e., \( v \in \{ \uparrow, \downarrow \} \), we may start with the spin singlet,

\[
|S_{ij}\rangle \equiv \frac{1}{\sqrt{2}} (c_{\uparrow i}^\dagger c_{\downarrow j}^\dagger - c_{\downarrow i}^\dagger c_{\uparrow j}^\dagger) |0\rangle ,
\]

(14a)

with \( |0\rangle \) the vacuum state with no particles. From the above, \( |S_{ij}\rangle \) is also a charge singlet. Then the creation of a particle-hole pair, i.e.,

\[
|C_{ij}\rangle \equiv \Pi_{ij;S}^{\bar{n} + 1} (|S_{ij}\rangle) = \frac{1}{\sqrt{2}} (c_{\uparrow i}^\dagger c_{\uparrow j}^\dagger - c_{\downarrow i}^\dagger c_{\downarrow j}^\dagger) |0\rangle ,
\]

(14b)
still yields a singlet, both in the SU(2) charge as well as SU(2) spin symmetry [note that the raising operator $C_i^+ \equiv s_i^+ c_i^+ \tilde{c}_i^+$, within SU(2) charge comes with alternating sign factors $s_i$ on a bipartite lattice, such that nearest neighbors have the opposite sign [15]; then with $C_{in}^\pm \equiv C_i^+ + C_j^+$ and the lowering operators $C_i^- \equiv (C_i^+)^\dagger$, given $|C_{ij}\rangle \propto (C_i^+ - C_j^+)|0\rangle$, it holds $C_{in}^\pm|C_{ij}\rangle = 0$].

From this we conclude that for the specific case $m = 1$, in contrast to $\Pi_{ij}^{n,1}$, it is the symmetrized operator $\Pi_{ij}^{n,1}$ in Eq. (13) that has scalar symmetry character in the spin sector and for $N = 2$ also in the charge sector, and thus respects larger symmetry. It is in this sense that we consider the symmetrized operator $\Pi_{ij}^{n,1}$ in Eq. (13) more suitable to define a simple scalar order parameter also for general $N$ (see Sec. III below).

### B. Effective interactions

The term $H_{\text{eff}}$ in Eq. (10) includes four types of second-order processes: two two-site and two three-site processes. The two-site processes are (i) hopping back and forth without actual particle transfer which leads to an $\hat{S}_i \cdot \hat{S}_j$ (ss) type flavor-flavor interaction, and (ii) hopping of a pair of particles between nearest-neighbor sites which relates to doublon-holon (dh) dynamics. The three-site processes appear on three neighboring sites in that two of them (say $j \neq k$) are nearest neighbors of site $i$. Then the three-site processes consist of (iii) hopping $j \rightarrow i$ and hopping $i \rightarrow k$, resulting in a correlated hopping (coherence) of a particle from site $j$ to $k$ that depends on the state of site $i$, and (iv) creation (annihilation) of a pair of particles at site $i$ originating from (splitting towards) sites $j$ and $k$, respectively. The latter represents two processes which are Hermitian conjugates of each other, i.e., doublon-holon creation and annihilation (dhx). Therefore, overall, we have

$$H_{\text{eff}} = H_{\text{ss}} + H_{\text{dh}} + H_{\text{coh}} + H_{\text{dhx}}.$$ \hspace{1cm} (15a)

By now, for simplicity, we also can role back the commutator in Eq. (10) to a plain product by reintroducing $m < 0$ in the sum, which leads to

$$H_{\text{ss}} = \sum_{i,j,n \atop m \neq 0,1} \frac{v^2}{mU} \Pi_{ij}^{n,m} (\Pi_{ij}^{n,m})^\dagger,$$

$$\equiv \sum_{i,j,n \atop m \neq 0,1} \frac{v^2}{mU} \left(-2\tilde{S}_i \cdot \tilde{S}_j + \frac{\hat{n}_i (N - \hat{n}_j)}{N}\right) P_{i,n} P_{j,n-m-1},$$

$$H_{\text{dh}} = \frac{v^2}{2U} \sum_{i,j,n} \left(\Pi_{ij}^{n,1} + \Pi_{ji}^{n,1}\right) \cdot (\Pi_{ij}^{n,1} + \Pi_{ji}^{n,1})^\dagger,$$

$$\equiv \frac{2v^2}{U} \sum_{i,j,n} \Pi_{ij}^{n,1} (\Pi_{ij}^{n,1})^\dagger.$$ \hspace{1cm} (15b)

Each term above will be derived and discussed next.

The effective spin-spin interaction $H_{\text{ss}}$ originates from

$$H_{\text{ss}} = \sum_{ij} \sum_{m' \atop v'=0,1} \frac{|\langle ij \rangle|^2}{mU} \tilde{c}_{i,v'} \tilde{c}_{j,v-m'} \tilde{c}_{j,v-m'}. \quad (15c)$$

which together with Eq. (11) yields Eq. (15b). Here the $m = 1$ term has been deliberately excluded, which may appear artificial, at first glance. After all, it represents a second-order hopping process that leaves the charge configuration and hence one may assign to $H_{\text{ss}}$. Nevertheless, for symmetry reasons, it will rather be associated with $H_{\text{dh}}$, as explained below. The flavor-flavor interaction in the first line of Eq. (15b) can be written in terms of SU(N) spin operators, since

$$\Pi_{ij}^{nm} (\Pi_{ij}^{nm})^\dagger = \sum_{v,v'} \frac{|\langle ij \rangle|^2}{mU} c_{ij,v} c_{j,v-m'} c_{j,v-m'}^\dagger P_{i,n} P_{j,n-m-1}$$

$$= \left(-2\tilde{S}_i \cdot \tilde{S}_j + \frac{\hat{n}_i (N - \hat{n}_j)}{N}\right) P_{i,n} P_{j,n-m-1},$$

where $\tilde{S}_i = \frac{1}{2} \sum_{v,v'} c_{ij,v}^\dagger \tilde{G}_{v,v'} c_{ij,v}$ is the SU(N) generalization of the spin operator, and $\tilde{G} = (G_1, \ldots, G_{N^2-1})$ is the set of SU(N) symmetry generators in the defining representation with the conventional normalization $\text{Tr}(G_a G_b) = 2\delta_{ab}$. Here we have used the identity,

$$\sum_{v,v'} c_{ij,v}^\dagger \tilde{G}_{v,v'} c_{ij,v} = 2\tilde{S}_i \cdot \tilde{S}_j + \frac{1}{N} \hat{n}_i \hat{n}_j,$$

having $N$ symmetric flavors. This leads to the second line in Eq. (15b).

The effective doublon-holon term $H_{\text{dh}}$ in Eq. (15c) originates from the pair hopping,

$$\hat{H}_{\text{dh}} = \sum_{ij} \sum_{m \atop v' \atop v} \frac{v^2}{mU} \tilde{c}_{ij,v} \tilde{c}_{ij,v-m'} c_{ij,v-m'}^\dagger \tilde{c}_{ij,v-m'} \tilde{c}_{ij,v-m'}, \quad (15d)$$

$$\equiv \frac{v^2}{U} \sum_{i,j,n} \Pi_{ij}^{n,1} (\Pi_{ij}^{n,1})^\dagger,$$ \hspace{1cm} (15e)

where the tilde on $\hat{H}_{\text{dh}}$ indicates the initially strict constraint to the transfer of a pair of particles. In order for the Coulomb interaction energy before and after the second-order process of a pair hopping to be the same, the charge configurations must be the same, yet reversed. This is the underlying natural reason for obtaining the constraint $m = 1$.

Now as discussed with Eqs. (13) and (14) above, for this specific case of $m = 1$, the individual terms in Eq. (17)
do not respect the SU(2)$_{\text{charge}}$ symmetry if present. In the
same manner, as a $\tilde{C}_i \cdot \tilde{C}_j$ interaction, with $\tilde{C}_j$ the pseudospin
operator in the particle-hole channel for $N = 2$, includes a $\tilde{C}_i^\dagger \tilde{C}_j^\dagger$ term that leaves the local charge configuration intact, it
is desirable to symmetrize Eq. (17). Therefore based on the
earlier discussion with Eqs. (13) and (14), above, we define

$$H_{dh} \equiv \tilde{H}_{dh} + \frac{v^2}{U} \sum_{i,j,n} \tilde{\Pi}_{ij}^{(n)} \langle \tilde{\Pi}_{ij}^{(n)} \rangle = \frac{2v^2}{U} \sum_{i,j,n} \tilde{\Pi}_{ij}^{(1)} \langle \tilde{\Pi}_{ij}^{(1)} \rangle.$$

Here the term added to $\tilde{H}_{dh}$ exactly recovers the $m = 1$ term
that has been already intentionally excluded from Eq. (15b)
above exactly for this reason.

For the case $N = 2$ with particle-hole symmetry then, $H_{ss}$
and $H_{dh}$ reduce to [4]

$$H_{ss} = \frac{v^2}{U} \sum_{(i,j)} \langle \tilde{S}_i \cdot \tilde{S}_j \rangle - P_1 P_\parallel,
$$

$$H_{dh} = \frac{2v^2}{U} \sum_{(i,j)} (c_i^\dagger c_j^\dagger c_j c_i + P_1 P_\parallel) + (i \leftrightarrow j)
= \frac{v^2}{U} \sum_{(i,j),v',v} \langle h_{ix} d_{jv}^\dagger h_{jv}^\dagger d_{jv} h_{iv}^\dagger d_{iv}^\dagger \rangle,
$$

where the flavor operator $\tilde{S}_i$ reduces to the standard SU(2) spin
operator $\hat{S}_i$, and $(i,j)$ indicates nearest neighbor pairs of sites.
In this case, the only remaining terms are $n = 1$ and $m = -1$
for Eq. (15b), and $n = n + 1 = 2$ for Eq. (15c). Here $H_{ss}$
and $H_{dh}$ can also be written as the projectors,

$$H_{ss} = \frac{-4v^2}{U} \sum_{(i,j)} \langle S_{ij} \rangle \langle S_{ij} \rangle,
$$

$$H_{dh} = \frac{4v^2}{U} \sum_{(i,j)} \langle C_{ij} \rangle \langle C_{ij} \rangle,$$

with $|S_{ij}\rangle$ and $|C_{ij}\rangle$ as defined in Eq. (14).

The three-site effective interactions in Eq. (15d) and
Eq. (15e), finally, are derived in complete analogy to the above
without any further ado.

C. Interpretation in terms of second-order perturbation theory

Though the effective Hamiltonian in Eq. (10) is derived
by employing the high-frequency expansion from Floquet
theory, it can be understood in an easier way. Indeed, the
term $H_{evn} H_{c,-m} / mU$ simply describes a second-order virtual
process in which an intermediate state differs in energy from
the initial and the final states by $-mU$ due to the Coulomb
interaction $H_U$. The way in which such second-order terms are
included into the effective Hamiltonian is similar to what is
done in the perturbation theory approach to the SWT [16,17].

However, there is a subtle difference. In the perturbation
theory approach, the intermediate state has clearly higher
energy than those of the initial and the final states. Here,
in contrast, the terms $H_{evn} H_{c,-m} / mU$ with $m > 0$ are also
incorporated in Eq. (10), that is, the intermediate state can
have “lower” interaction energy by $-mU < 0$. At first glance,
it seems to be contradictory to the spirit of the SWT that the
virtual process, starting from and ending at a low-energy sub-
space, should involve an intermediate state of higher energy.

To resolve this, we remark that the denominator $mU$
is the energy difference measured by only the local Coulomb
interaction $H_U$, not by the full Hamiltonian that also includes
kinetic energy. The Fermi-liquid ground state in the metallic
phase involves local charge fluctuations, which give rise to
its metallicity. Acting with $H_{c,-m} (m > 0)$ onto this ground
state will decrease the Coulomb energy $\langle H_U \rangle$ by $mU$, but
increase the total energy $\langle H \rangle$, since it is not the ground state
anymore. Thus the intermediate state implied by the terms
$H_{evn} H_{c,-m} / mU$ of $m > 0$ (e.g., $H_{dh}$ originating from $m = 1$)
has higher energy. On the other hand, in the insulating phase,
the ground state is mainly spanned by the basis in which the
lattice sites are filled with the average integer occupation $\bar{n}$.
The contribution of doublons and holons to the ground state is finite
but small, as shown in Ref. [18]. Thus, contrary to the metallic
case, the terms $H_{evn} H_{c,-m} / mU$ of $m > 0$ become much less
relevant to the low-energy subspace in the insulating phase.

Therefore the summation over all possible values of $m$,
positive as well as negative, is not contradictory at all. It
is rather an unbiased way of including all second-order
processes, without pre-defining any low-energy subspace. In
other words, the construction of the effective Hamiltonian
in Eq. (10) represents all possible “slow” processes, i.e.,
dynamics within an energy window of narrow width $-v^2 / U$.
In contrast, the $t$-$J$ model does not contain the doublon-holon
term $H_{dh}$, since the terms of $m > 0$ in Eq. (10) are neglected
by the assumption that the half-filled subspace is low-energy
subspace. In this sense, the $t$-$J$ model provides an incomplete
description for the metallic phase.

III. MEAN-FIELD DECOUPLING SCHEME FOR
DOUBLON AND HOLON CORRELATORS

We utilize the equations of motion approach to compute
the correlators of the projected particle operators $\tilde{c}_{i\nu}$ whose
time evolutions are generated by the effective Hamiltonian of
the SU(4) Hubbard model. The effective Hamiltonian is given
by $H_{ef}$ in Eqs. (10) and (15) while neglecting terms of order
$O(v^3 / U^2)$. The equation of motion for the correlator in the
frequency domain is given by

$$\omega^+ \langle \tilde{c}_{i\nu}^\dagger \tilde{c}_{j\nu'}^\dagger \rangle_{\omega} = \langle \tilde{c}_{i\nu}^\dagger \tilde{c}_{j\nu'}^\dagger \rangle - \langle \tilde{H}_{\text{eff}} \tilde{c}_{i\nu}^\dagger \tilde{c}_{j\nu'}^\dagger \rangle_{\omega},
$$

(19)

where $\langle A \rangle_{\omega} \equiv \int dt e^{i\omega t} \langle A \rangle$, with $\omega^+ \equiv \omega + i0^+$
and $\langle A \rangle_{\omega} = G_{AB}(\omega) \equiv \langle \{ A(t), B(0) \} \rangle_{\omega}$, assuming
fermionic operators $A$ and $B$, i.e., containing an odd number of
(projected) fermionic creation and annihilation operators. For
bosonic operators $A$ and $B$, such as for the charge susceptibility
$\chi_{\delta}(\omega) \equiv \langle \hat{n} \delta \hat{n} \rangle_\omega$ the anticommutator
would be replaced by the commutator $\langle [A(t), B] \rangle_{\omega}$.
In Eq. (19) we consider general locatons $i$ and $i'$ in the correlator which
will be required for the Fourier transform to momentum space later.
Since $H_{ef}$ is not quadratic, the equations of motion generated
by Eq. (19) do not close.

The mean-field and the decoupling approximations to close
the equations of motion are as follows. First, we regard the
paramagnetic metallic ground state as the condensate of the
pair of doublon- and holon-like excitations, e.g., created by the action of $\Pi_{ij}^{\dagger}$ [cf. Eq. (13)] which represents a projected part of the hopping Hamiltonian $H_v$ [cf. Eqs. (8a) and (12)]. Following the discussion in Secs. II A 4 and II B, the condensate also respects charge and spin symmetries, i.e., does not break them in the metallic phase. (In the insulating phase, on the other hand, the doublon-holon pair does not condense, since charge fluctuations are largely suppressed; see Sec. II C above.)

Accordingly we define the mean-field variables,

$$\Delta_n = -\frac{v}{U} \sum_{ij} \left( \Pi_{ij}^{\dagger} \Pi_{ij} \right),$$

(20)

which is positive when the expectation value is taken with the Fermi-liquid ground state of the metallic phase. For $U = 0$, it is clear that the expectation value of the hopping term is negative, $\langle H_v \rangle = \sum_{ij} v_{ij} \langle c_i^{\dagger} c_j \rangle < 0$, by filling states with negative one-particle energies. The operator $\Pi_{ij}^{\dagger}$ annihilates a doublon-holon pair, is nothing but a summand of the hopping Hamiltonian

$$H_{dh} \approx -\frac{v}{U} \sum_{ij} \Delta_n \left( \Pi_{ij}^{\dagger} + \Pi_{ji}^{\dagger} \right) + H.c.$$  

(21)

For the SU(2) case, there is only one type of pair excitations, namely for $n = 2$ (due to the range of $n$), i.e., $\Delta_{2}\Delta_n = \Delta_{n\Delta^2}$.

Second, we decouple the flavor and charge operators from the correlators of interest, since we focus on the subpeaks on the intermediate energy scale away from those of the quasiparticle peak and the Hubbard bands. Charge fluctuations explore high energy scales on the order of $U$, i.e., the region of the Hubbard bands, which are integrated out by the generalized SWT. Flavor fluctuations [equivalent to spin in the case of $N = 2$ flavors], on the other hand, typically remain in the low-energy sector. Consistently, in the local density of states (spectral function) the spin fluctuations predominantly contribute to the quasiparticle peak around $\omega = 0$, whereas the Hubbard side bands are largely integrated out except for their inner subpeak structure. This separation of the energy scales for charge and spin fluctuations appears as the separation of the peak positions of charge and spin susceptibilities; see Fig. 1 of Ref. [4].

Now the commutator $[H_{df}, \tilde{c}_{i\nu n}]$ in Eq. (19) results in a sum of two- and three-site terms, say $O_i O_j$ or $O_i O_j O_k$, which group all local operators acting on sites $i$, $j$, and $k$, respectively. Moreover, these local operators, say $O_i$ on site $i$, comprise one, two, or three projected particle operators $\tilde{c}_{i\nu n}$. The local operators made of two projected operators can be classified into three types: pair creation and annihilation $(\tilde{c}_{i\nu n} \tilde{c}_{i'\nu' n+1})^{\dagger}$, spin flip $\tilde{c}_{i\nu n}^{\dagger} \tilde{c}_{i'\nu'n}$ ($\nu \neq \nu'$), and charge measurement $\tilde{c}_{i\nu n}^{\dagger} \tilde{c}_{i'\nu'n}$ $\propto P_{i\nu}$.

We decouple such local operators made of two projected operators, say $O_j$, from the correlators, e.g., $\langle O_j' O_j \rangle_{\omega} \approx \langle O_j' \rangle_{\omega} \langle O_j \rangle_{\omega}$. Since the metallic ground state conserves the total number of particles of each flavor $\sum n_{i\nu}$, and is not flavor polarized, only the charge measurement type of local operator has finite expectation value. Hence we need to expand the $\Pi$ terms in $H_{df}$ in favor of the new shortcuts,

$$A^a_{iv} = \tilde{c}_{i\nu n}^{\dagger} \tilde{c}_{i'\nu'n} \rightarrow \left( A^a_{iv} \right) = \frac{n}{N} \langle P_{i\nu} \rangle,$$

(22a)

$$B^a_{iv} = \tilde{c}_{i\nu n}^{\dagger} \tilde{c}_{i'\nu'n} \rightarrow \left( B^a_{iv} \right) = \frac{N - n + 1}{N} \langle P_{i\nu} \rangle_{i \neq -1},$$

(22b)

$$\tilde{c}_{i\nu n}^{\dagger} \tilde{c}_{i'\nu'n} \rightarrow \left( \tilde{c}_{i\nu n}^{\dagger} \tilde{c}_{i'\nu'n} \right) = 0 \text{ if } \nu \neq \nu',$$

(22c)

$$\tilde{c}_{i\nu n} \rightarrow \left( \tilde{c}_{i\nu n} \right) = 0.$$  

(22d)

Furthermore, we neglect the three-site terms $O_i O_j O_k$ in the commutator $[H_{df}, \tilde{c}_{i\nu n}]$ where all $O_i$, $O_j$, and $O_k$ are made of an odd number of projected particle operators. We presume that these approximations can be compensated by renormalizing the system parameters.

With this, the first term on the right-hand side of Eq. (19) becomes

$$\langle \left[ \tilde{c}_{i\nu n}, \tilde{c}_{i'\nu'n} \right] \rangle = \delta_{i\nu i'\nu'} \delta_{i\nu i'\nu'} \langle A^a_{iv} + B^a_{iv} \rangle.$$  

Note that the $\tilde{c}$ operators do not obey fermionic commutator relations, hence the result here is not just given by canonical fermionic commutator relations.

Now we expand the commutator $[H_{df}, \tilde{c}_{i\nu n}]$ in Eq. (19) term by term. From Eq. (10), we have

$$[H_{\mu}, \tilde{c}_{i\nu n}] = -\mu \sum_{i' m} [n' P_{i' m}, \tilde{c}_{i\nu n}] = \mu \tilde{c}_{i\nu n},$$

(23)

$$[H_{\nu,0}, \tilde{c}_{i\nu n}] = \sum_{i' j' \nu' n'} v_{j' j} \left( \Pi_{i' j' \nu' n'}^{\dagger} \tilde{c}_{i\nu n} \right) \approx -\left( A^a_{iv} + B^a_{iv} \right) \sum_{j} v_{ij} \tilde{c}_{i' j' n'},$$

(24)

where $\ldots$ means the terms to be neglected via the decoupling approximation in Eq. (22). The sum $\langle A^a_{iv} + B^a_{iv} \rangle$ in Eq. (24) is the remnant of the commutator. Similarly for the doublon-holon term,

$$[H_{dh}, \tilde{c}_{i\nu n}] \approx -\frac{v}{U} \sum_{n'} \left[ \Delta_n \Pi_{i j}^{\dagger} + \Delta_n^{*} \left( \Pi_{i j} \right)^{\dagger} + \ldots \right] \tilde{c}_{i\nu n} \approx \left( A^a_{iv} + B^a_{iv} \right) \sum_{j} v_{ij} \left( \frac{\Delta_n}{U} \tilde{c}_{i\nu n+1} + \frac{\Delta_n^{*} + 1}{U} \tilde{c}_{i\nu n-1} \right),$$

(25)

and for the flavor-flavor interactions,

$$[H_{df}, \tilde{c}_{i\nu n}] = \sum_{i' m} \sum_{n' m' \neq 0,1} \frac{v^2}{m U} \left[ \Pi_{i' j' \nu' n'}^{\dagger} \left( \Pi_{i' j' \nu' n'}^{\dagger} \right)^{\dagger} + \Pi_{i' j' \nu' n'}^{\dagger} \left( \Pi_{i' j' \nu' n'}^{\dagger} \right)^{\dagger} \right] \tilde{c}_{i\nu n}.$$

(26)
\[
\sum_{j'v} \sum_{m \neq 0,1} \frac{|v_{ij}|^2}{mU} \left( (A_{ij}^{m-1} B_{j'v}^{m-1} - B_{j'v}^{m+1} A_{ij}^{m+1}) \tilde{c}_{i,v} - \tilde{c}_{i,v} (A_{ij}^{m+1} B_{j'v}^{m+1} - B_{j'v}^{m-1} A_{ij}^{m-1}) \right) + \ldots
\]

\[
\approx \sum_{j} \sum_{m \neq 0,1} \frac{|v_{ij}|^2}{mU} \left((n - 1)|B_{j'v}^{m-1}| + (N - n + 1)|A_{ij}^{m+1} - n|B_{j'v}^{m-1} - (N - n)|A_{ij}^{m+1} + 1\right) \tilde{c}_{i,v} \tag{26}
\]

where the sum over \(v'\) survives the commutator in the first line, since the \(\Pi\)'s include projectors. The mean-field averaging in the third line is performed on the quadratic operators \(A\) and \(B\) at site \(j\) only. Consequently, with \(<B_{j'v}^{m-1}\>\) assumed independent of \(v'\) (hence the brackets around the prime), the sum over \(v'\) can be performed for the three operators acting on site \(i\): e.g.,

\[
\sum_{v'} A_{ij}^{m-1} \tilde{c}_{i,v} = \sum_{v'} \tilde{c}_{i,v} \cdot P_i - 1 - \tilde{c}_{i,v} = (n - 1) \tilde{c}_{i,v}.
\]

Finally for the three-site term, with Eq. (15a), we have

\[
[H_{3\text{-site}}, \tilde{c}_{i,v}] = [H_{\text{coh}}, \ldots, \tilde{c}_{i,v}]^{(15d)} = \sum_{k,j
ot= i} \sum_{m \neq 0} \frac{v_{ij}^2}{mU} \left[ \Pi_{k,j}^{m} (\Pi_{k,i}^{m})^\dagger + \Pi_{k,j}^{m} (\Pi_{k,j}^{m})^\dagger + \ldots \right] \tilde{c}_{j,v} \tag{27}
\]

where for the last line we relabeled \(m \to -m\) on the second part of the second line. With the approximations above, the system of equations of motion is in closed form now.

### A. The case of \(N = 2\)

In this subsection, we consider the example of the SU(2) Hubbard model at half filling. It holds by symmetry then that \(\mu = 0\), and \((P_{10}) = (P_{12}) = (1 - (P_{11})) / 2\). Therefore \((A_{ij}^{m} + B_{ij}^{m}) = \frac{1}{2}\) for \(n = 1, 2\). The projected particle operators are doublon and holon operators, \(d_{iv} = \tilde{c}_{iv, n = 2}, h_{iv}^\dagger = \tilde{c}_{iv, n = 1}\), and there is only one mean-field variable \(\Delta_{n=2} = \Delta_{dh}\). From the above derivation for general \(N\), we obtain

\[
-[H_{\text{eff}}, d_{iv}] \approx \sum_{j} \frac{v_{ij}}{2} \left[d_{iv} = \frac{\Delta_{dh}}{U} h_{iv}^\dagger + \frac{2v_{ij}}{U} \langle P_{11} \rangle d_{iv} \right] + \sum_{k,j \not= i} \frac{v_{ij} v_{kl}}{4U} d_{ij}, \tag{28a}
\]

\[
-[H_{\text{eff}}, h_{iv}^\dagger] \approx \sum_{j} \frac{v_{ij}}{2} \left[h_{iv}^\dagger = \frac{\Delta_{dh}}{U} d_{iv} - \frac{2v_{ij}}{U} \langle P_{11} \rangle h_{iv}^\dagger \right] - \sum_{k,j \not= i} \frac{v_{ij} v_{kl}}{4U} h_{ij}^\dagger \tag{28b}
\]

In this system of equations, only the doublon and holon operators of the same flavor index \(v\) are related; hereafter, we drop the index \(v\) for simplicity.

For the DMFT calculations in Ref. [4], we considered a lattice which has semielliptic density of states, \(\rho_0(\omega) = \frac{1}{\pi \sqrt{D^2 - \omega^2}}\). The Bethe lattice has such a density of states, but solving the system of equations in Eq. (28) on the Bethe lattice is not simple; the Fourier transform is not applicable to the Bethe lattice since it is not translationally invariant in Euclidean space. Instead, we consider the hypercubic lattice in infinite dimensions (where one can use the Fourier transform) which approximates the semielliptic density of states for small energies. The density of states for such hypercubic lattice is Gaussian [19],

\[
\rho_{\text{he}}(\omega) = \frac{1}{\sqrt{2\pi \Sigma}} e^{-\omega^2 / (2\Sigma^2)}, \tag{29}
\]

where \(\Sigma\) scales as \(1 / \sqrt{z}\) depending on coordination number \(z \to \infty\). Here we set \(D = \sqrt{3} v_0\) [contrary to \(D = 2v_0 \sqrt{2}\) for the semielliptic \(\rho_0(\omega)\)] so that two density of states \(\rho_0(\omega)\) and \(\rho_{\text{he}}(\omega)\) are the same for small energies \(|\omega| \ll D\) up to the overall factor,

\[
\rho_0(\omega) = \frac{2}{\pi D} \left(1 - \frac{\omega^2}{2D^2}\right) + O(\omega^4 / D^4),
\]

\[
\rho_{\text{he}}(\omega) = \frac{1}{\sqrt{2\pi} D} \left(1 - \frac{\omega^2}{2D^2}\right) + O(\omega^4 / D^4). \tag{30}
\]

We introduce the doublon and holon operators in momentum space,

\[
d_{iv} = \sqrt{\frac{2}{N_s}} \sum_{1 \leq \alpha \leq 4} e^{-i p \cdot r_i} d_i, \quad h_{iv}^\dagger = \sqrt{\frac{2}{N_s}} \sum_{1 \leq \alpha \leq 4} e^{-i p \cdot r_i} h_i,
\]

where we have dropped the flavor index \(v\) as noted after Eq. (28). Here \(p\) is the linear momentum (using units of \(\hbar = 1\)), \(N_i\) the total number of lattice sites, and \(r_i\) the location of site \(i\). Given the nearest-neighbor hopping on a hypercubic lattice, the hopping connects two bipartite sublattices, labeled \(\alpha = A, B\).
We now rephrase Eq. (28) in matrix form. With
\[
\tilde{O}_p = (d_{pA} h_{pA}^\dagger + d_{pB} h_{pB}^\dagger),
\]
(31a)
\[
|G_p(\omega)|_{mn} = (O_{pm} \parallel O_{pn})_{4\nu},
\]
(31b)
and using the relations for a periodic inversion symmetric lattice,
\[
\epsilon_p = \sum_j v_{ij} e^{i j (r_i - r_j)} = \epsilon_{-p},
\]
(32a)
\[
\epsilon_p^2 - D^2 = \sum_{j, k \neq i} v_{ij} v_{jk} e^{i j (r_{i} - r_{k})},
\]
(32b)
we obtain (where scalar numbers are implicitly multiplied by the four-dimensional identity matrix \(I_{4\times4}\)),
\[
[\omega^+ - H_p]G_p(\omega) = \frac{1}{2},
\]
(33a)
where
\[
H_p = \frac{\epsilon_p}{2} \begin{pmatrix} 1 & 1 \\ 1 & 1 \end{pmatrix} - \frac{\epsilon_p}{2U} \begin{pmatrix} \Delta^+_d & \Delta^+_h \\ \Delta^-_d & \Delta^-_h \end{pmatrix} + \frac{D^2}{2} (4P_{11} - 1) + \frac{\epsilon_p}{4U} \begin{pmatrix} 1 & -1 \\ -1 & 1 \end{pmatrix},
\]
(33b)
with zero-matrix elements not shown, for readability. From this matrix equation, we compute the local correlators as follows. For an arbitrary but fixed value of noninteracting kinetic energy \(\epsilon_p\), we diagonalize \(H_p\) to obtain energy eigenvalues \(\lambda_{\pm}\) and corresponding eigenvectors \(\vec{u}_{\pm}\) \((k = 1, \ldots, 4)\). Figure 1 shows for how \(\lambda_{\pm}\) depends on \(U\) and \(\epsilon_p\). Then, for each \(k\), the \((m,n)\) element of the \(4 \times 4\) matrix \(\vec{u}_{\pm} \vec{u}_{\mp}^\dagger / 2\) gives the contribution to the imaginary part of the correlators, i.e.,
\[
[A_p(\omega)]_{mn} = \frac{1}{\pi} \text{Im} \langle G_p(\omega) \rangle, \text{ at energy } \omega = \lambda_{\pm} \text{ as follows:}
\]
\[
[A_p(\omega)]_{mn} = \sum_{k=1}^4 \left[ \frac{\vec{u}_{\pm}(\epsilon_p) \vec{u}_{\mp}^\dagger(\epsilon_p)}{2} \right]_{mn} \delta(\omega - \lambda_{\pm}(\epsilon_p)),
\]
where the factor 1/2 to the matrix \(\vec{u}_{\pm} \vec{u}_{\mp}^\dagger / 2\) originates from the right-hand side of Eq. (33a), and the indices \(m\) and \(n\) are defined by Eq. (31). With this, we obtain the local correlator in real space, say at site \(i\),
\[
[A_{i}(\omega)]_{mn} = \frac{1}{\pi} \text{Im} \langle O_m \parallel O_n^\dagger \rangle_{\omega} = \int_\omega^\infty d\epsilon_p \rho_{hc}(\epsilon_p) [A_p(\omega)]_{mn}
\]
\[
= \int_\infty^\omega d\epsilon_p \rho_{hc}(\epsilon_p) [A_p(\omega)]_{mn}
\]
\[
= \int_\infty^\omega d\epsilon_p \sum_{k=1}^4 \left[ \frac{\vec{u}_{\pm}(\epsilon_p) \vec{u}_{\mp}^\dagger(\epsilon_p)}{2} \right]_{mn} \times \rho_{hc}(\epsilon_p) \delta(\omega - \lambda_{\pm}(\epsilon_p)),
\]
(34)
where \(\tilde{O}_i\) is the same as in Eq. (31), except the replacement \(\pm p \rightarrow i\). In practice, we solve the analytical expressions in Eq. (34) numerically. For this, (i) we take a grid for \(\epsilon_p\), and replace the integral with a numerical summation. (ii) We diagonalize the matrix \(H_p\) for each value of \(\epsilon_p\). Then the contribution to \([A_p(\omega)]_{mn}\) will be given as the collection of \(\delta\) functions at \(\lambda_{\pm}(\epsilon_p)\). Finally, (iii) we replace the \(\delta\) functions in frequency space with the Gaussians of a finite but narrow width that just interpolates the discrete intervals.

The components \([A_p(\omega)]_{mn}\) with \((m,n) = (1,1)\) and \((2,2)\) [or equivalently \((m,n) = (3,3)\) and \((4,4)\)] are equivalent to the spectral functions \(A_{dd}(\omega) = -\frac{1}{\pi} \text{Im} \langle \tilde{d}_{i\nu} \parallel \tilde{d}_{i\nu}^\dagger \rangle_{\omega}\) and \(A_{dh}(\omega) = -\frac{1}{\pi} \text{Im} \langle \tilde{h}_{i\nu} \parallel \tilde{d}_{i\nu}^\dagger \rangle_{\omega}\), respectively, as shown in Fig. 1. They exhibit peaks at \(\omega = \pm \omega_{dh}\). Due to the operator identity \(\tilde{c}_{i\nu} = \tilde{d}_{i\nu} + \tilde{h}_{i\nu}\), for the case \(N = 2\), the sum of the correlation functions of doubloons and holons is equivalent to the Green’s function of the particle, that is,
\[
A(\omega) = A_{dd}(\omega) + A_{dh}(\omega) + A_{dh}(\omega) + A_{hh}(\omega),
\]
(35)
where \(A(\omega)\) is the local spectral function. In the given SU(2) case, the particle-hole symmetry results in the symmetry of the correlation functions, \(A_{dd}(\omega) = A_{hh}(\omega)\) and \(A_{dh}(\omega) = A_{hd}(\omega)\). Thus the peaks of correlation functions \(A_{dd}(\omega)\) and \(A_{dh}(\omega)\) correspond directly to the peak features in \(A(\omega)\).

The mean-field decoupling scheme underlying Eq. (33) above deserves a few comments. First, by the specific approximations taken, we cut out both the low-energy spin dynamics and high-energy charge dynamics. Therefore, in contrast to the numerical results presented in Ref. [4], the analytically obtained curves in Fig. 1 capture neither the low-energy peak at the Fermi energy near \(\omega = 0\) related to spin dynamics, nor the Hubbard bands, as indicated by the gray shaded areas in Fig. 1.

Second, the mean-field decoupling scheme as introduced above is at the level of equations of motion for correlation.
functions that take two parameters, namely $\langle P_1 \rangle$ and $\Delta_{\text{db}}$, as input. Solving these mean-field equations for the correlation functions does not offer a simple way to recompute $\langle P_1 \rangle$ and $\Delta_{\text{db}}$, e.g., to determine these parameters self-consistently, contrary to other mean-field approaches such as the Bardeen-Cooper-Schrieffer (BCS) theory of superconductivity. Instead, the values of $\langle P_1 \rangle$ and $\Delta_{\text{db}}$ do depend on the dynamics at the decoupled energy scales. For example, our first parameter $\langle P_1 \rangle$ is directly related to the charge susceptibility $\chi_c(\omega)$ at all frequencies since, e.g., at half filling and $T = 0$ [20],

$$\int_0^\infty d\omega \chi_c(\omega) = (\langle \delta \hat{n} \rangle^2) = \langle P_0 \rangle + \langle P_2 \rangle = 1 - \langle P_1 \rangle.$$

(36)

Indeed, $\chi_c(\omega)$ has a peak largely overlapping with the upper Hubbard band (e.g., see Fig. 1 in Ref. [4]). As a sensible choice for this mean-field parameter, in practice, we simply take the (exact) numerical data for $\langle P_1 \rangle$ from our DMFT calculations (see Fig. S2 in Ref. [4]).

Similarly, the second parameter in our mean-field decoupling scheme, $\Delta_{\text{db}} = \frac{1}{2} \sum_{i,\nu} (d_{i\nu}h_{j\nu} + d_{j\nu}h_{i\nu})$, is a static expectation value with respect to the ground state of the low-energy effective Hamiltonian. Thus the value of $\Delta_{\text{db}}$ can be interpreted as a property of Fermi-liquid quasiparticles. Furthermore, given the general property $A_{\text{dd}}(\omega = 0) = A_{\text{dd}}(\omega = 0) = 1/2\pi$ which is constant within the metallic phase for arbitrary $U < U_c$ at $T = 0$, as also supported by our DMFT results in Ref. [4], we take this as an indication that the mobility of the quasiparticles is rather independent of $U$ (similarly, the transmission probability in impurity models at $T = 0$ is related to the value of the spectral function $A(\omega)$ at $\omega = 0$ [21], and not the width of the quasiparticle peak around $\omega = 0$). Accordingly we choose a constant $\Delta_{\text{db}} = \frac{1}{2} \sum_{i,\nu} (d_{i\nu}h_{j\nu} + d_{j\nu}h_{i\nu})$ for $U < U_c$. We tested different values of $\Delta_{\text{db}}$ as a free parameter, and found that with $\Delta_{\text{db}} = U_c$, we can reproduce the DMFT results in Ref. [4] of the subpeak position $\Delta_{\text{db}}$ and the width of the quasiparticle peak $\omega_{\text{db}}$, respectively, by using Young tableaux. The building blocks of $H_{\text{db}}$ are the projected hoppings $\Pi_{ij}^{\text{db}} = (P_0 P_{\text{db}} P_{\text{db}} - m) (\sum_{\nu} c_{i\nu}^{\dagger} c_{j\nu}) (P_{\text{db}} P_{\text{db}} - m)$ [cf. Eq. (11)].

Table I shows the SU($N$)$_{\text{flavor}}$ symmetry labels and the corresponding degeneracies of the two-site interactions. Here we use the degeneracy, i.e., dimension, of a multiplet as an additional label to the Young tableau, where $0$ refers to the dual representation of $q$. Given a single local flavor index $v = 1, \ldots, N$ of fermionic character, the local multiplet for a single lattice site necessarily needs to be antisymmetric, i.e., a single column in a Young tableau. The third column for $P_{\text{db}} P_{\text{db}}$ then combines two such Young tableaux at the specific integer filling $\bar{n} \equiv (\bar{n}) = \lfloor N/2 \rfloor$ chosen here as well as in the DMFT calculations in Ref. [4]. On the left-hand side of the equations in the fourth column, one particle (box) has been transferred across the two sites, as compared with the left-hand side tableaux in the third column. The last column shows the intersection of the resulting symmetry sectors of the previous two columns, which thus represents the relevant block-diagonal symmetry sectors of $H_{\text{db}}$ and $H_{\text{ss}}$. This is identical with the result of the fourth column for $P_{\text{db}} P_{\text{db}} P_{\text{db}}$.

Table I: The Young tableaux describing the SU($N$)$_{\text{flavor}}$ symmetry sectors and their degeneracies for the projectors and the two-site interactions. Here we use the degeneracy, i.e., dimension, of a multiplet as an additional label to the Young tableau, where $0$ refers to the dual representation of $q$. Given a single local flavor index $v = 1, \ldots, N$ of fermionic character, the local multiplet for a single lattice site necessarily needs to be antisymmetric, i.e., a single column in a Young tableau. The third column for $P_{\text{db}} P_{\text{db}}$ then combines two such Young tableaux at the specific integer filling $\bar{n} \equiv (\bar{n}) = \lfloor N/2 \rfloor$ chosen here as well as in the DMFT calculations in Ref. [4]. On the left-hand side of the equations in the fourth column, one particle (box) has been transferred across the two sites, as compared with the left-hand side tableaux in the third column. The last column shows the intersection of the resulting symmetry sectors of the previous two columns, which thus represents the relevant block-diagonal symmetry sectors of $H_{\text{db}}$ and $H_{\text{ss}}$. This is identical with the result of the fourth column for $P_{\text{db}} P_{\text{db}} P_{\text{db}}$.

| $\bar{n}$ | $P_{\text{db}} P_{\text{db}}$ | $P_{\text{db}} P_{\text{db}} P_{\text{db}}$ | $H_{\text{ss}}, H_{\text{db}}$ |
|---|---|---|---|
| 2 | 1 | 1 | 1 |
| 3 | 1 | 1 | 1, 1 |
| 4 | 2 | 1 | 1 |

With increasing $N$, which originates from the larger SU($N$) flavor symmetry. As shown in Fig. 4 in Ref. [4], this eventually results in a wider peak at $\omega = 0$ due to the spin dynamics via $H_{\text{ss}}$, as well as more pronounced subpeaks on the inner edge of the Hubbard side bands due to doublon-holon dynamics via $H_{\text{db}}$.

For a more detailed analysis of relative degeneracies, we study the SU($N$) flavor symmetry properties of the two-site interaction terms $H_{\text{ss}}$ and $H_{\text{db}}$ in Eqs. (15b) and (15c), respectively, by using Young tableaux. The building blocks of $H_{\text{ss}}$ and $H_{\text{db}}$ are the projected hoppings $\Pi_{ij}^{\text{db}} = (P_{\text{db}} P_{\text{db}} - m) (\sum_{\nu} c_{i\nu}^{\dagger} c_{j\nu}) (P_{\text{db}} P_{\text{db}} - m)$ [cf. Eq. (11)]. In the joint Hilbert space of sites $i$ and $j$, $\Pi_{ij}^{\text{db}}$ is block diagonal in the symmetry sectors of the U($1$)$_{\text{charge}} \otimes$ SU($N$)$_{\text{flavor}}$ symmetry, since each of the terms above respects this symmetry.

When $U$ is large, charge configurations far away from the average occupation $\bar{n}$ are suppressed albeit still present even if the system is in the metallic phase. Then the relevant charge sectors are restricted to $(n_i, n_j) = (\bar{n}, \bar{n})$ for $H_{\text{ss}}$ and $(n_i, n_j) = (\bar{n} + 1, \bar{n} - 1), (\bar{n} - 1, \bar{n} + 1)$ for $H_{\text{db}}$. These charge configurations are connected by the elementary building block of $H_{\text{ss}}$ and $H_{\text{db}}$, namely $\Pi_{ij}^{\text{db}}$ and $\Pi_{ij}^{\text{db}}$.

Thus we will compute the symmetry sectors of the projectors $P_{\bar{n} \bar{n}} P_{\bar{n} \bar{n}}$ and $P_{\bar{n} \bar{n} \bar{n}} P_{\bar{n} \bar{n} \bar{n}}$ which act on the left or right of $\Pi_{ij}^{\text{db}}$, depending on the value of $m$. In this section, we focus on the filling $\bar{n} = (\bar{n}) = \lfloor N/2 \rfloor$ as considered in Ref. [4]. A generalization to arbitrary integer filling $\bar{n}$ is straightforward.

Table I shows the SU($N$)$_{\text{flavor}}$ symmetry labels and the corresponding degeneracies of the projectors and the two-site interactions.
interactions. Note that the $U(1)_{\text{charge}}$ symmetry labels are trivially the sum $n_i + n_j$. We observe that the SU($N$)$_{\text{flavor}}$ symmetry sectors for $P_\alpha P_{\bar{\beta}}$ and $P_\alpha P_{\bar{\beta}} P_j P_{\bar{\gamma}}$ are different, by comparing the third and the fourth columns in Table I. Therefore the symmetry sectors that are relevant for $H_{ex}$ and $H_{dh}$, are given by the common sectors, i.e., the intersection between the sectors for $P_\alpha P_{\bar{\beta}}$ and $P_\alpha P_{\bar{\beta}} P_j P_{\bar{\gamma}}$; see the last column in Table I.

For $N = 2$, we notice that the pair states onto which $H_{ex}$ and $H_{dh}$ project [cf. Eq. (18)] are in the singlet sector of the SU(2)$_{\text{flavor}}$ symmetry, that is, the spin-spin interaction prefers the spin singlet (with binding energy $-4v^2/U$) and the doublon-holon pair (once it exists, with excitation energy $4v^2/U$) is nondegenerate. On the other hand, the low-energy sectors for SU($N > 2$) have larger degeneracy, i.e., lie in symmetry sectors with larger multiplet dimensions. For $N = 3$, the doublon-holon pair excitation with energy $4v^2/U$ and the flavor-flavor bound state with energy $-4v^2/U$ are in the threefold degenerate sector $\mathbf{3}$, as seen from the last column in Table I. For $N = 4$, the pair excitations have two different energies, $4v^2/U$ and $12v^2/U$, in the 15-fold degenerate sector $\mathbf{15}$ and the nondegenerate singlet sector $\mathbf{1}$, respectively (see the last column in Table I). The flavor-flavor bound states are also in these two sectors with the respective binding energies $-4v^2/U$ and $-12v^2/U$.

This symmetry argument explains the strong enhancement of the subpeaks observed [4] in the local spectral functions $A(\omega)$ for larger $N$ (cf. Fig. 4 in Ref. [4]), compared with $N = 2$ case (cf. Fig. 1 in Ref. [4]). The subpeaks gain more spectral weight for larger $N$ and even become higher than the rest of the Hubbard bands for $N = 4$, consistent with the increasing degeneracy of doublon-holon pairs: 1 for $N = 2$, 3 for $N = 3$, and 15 $\oplus$ 1 for $N = 4$. On the other hand, the quasiparticle peak around $\omega = 0$ is also enhanced for larger $N$; the quasiparticle peak persists even at elevated $U$, supported by the degeneracy in the flavor-flavor terms that grows in the same way as the degeneracy of the doublon-holon terms. Overall then, by the sum rule conservation of local correlations functions, accordingly, the Hubbard bands have lower relative weight and height.

V. CONCLUSION

We have used a generalized SWT to obtain an effective low-energy Hamiltonian for multilayer Hubbard models which contains all the effective interactions up to order $O(1/U)$. Our straightforward approach avoids the need of determining the appropriate canonical transformation as required in previous SWT schemes [2], e.g., used for the derivation of the $t$-$J$ model.

Having derived the effective Hamiltonian, we interpreted the Fermi-liquid ground state of the paramagnetic metallic phase as the condensate of the doublon-holon pairs, and introduced a mean-field variable based on the expectation value of the doublon-holon pair annihilation operator. This mean-field approximation is analogous to the Bardeen-Cooper-Schrieffer (BCS) theory of superconductivity in which the expectation value of the Cooper pair annihilation operator is chosen as the superconducting order parameter. Thus the role of the doublon-holon interaction term is crucial here, reminiscent of the Cooper pair terms in the BCS Hamiltonian.

Then we computed the correlation functions of doublons and holons, focusing on the well-separated intermediate energy scale in between the low- and high-energy scales associated with the features in the local spectral function, namely the smaller scale for the quasiparticle peak and the larger scale for the Hubbard bands. Since these features are associated with the spin and charge degrees of freedom, respectively, we effectively used a mean-field decoupling of the spin and charge degrees of freedom from doublons and holons.

We observed subpeaks at finite frequency that are clearly associated with the doublon-holon dynamics. The numerical results shown in Ref. [4] and the symmetry argument in Sec. IV demonstrate that the subpeaks become more pronounced for larger number $N$ of particle flavors, since the doublon-holon excitation on a pair of nearest-neighbor sites gains access to a larger degenerate state space.

We expect that the subpeaks would be observable in photoemission spectroscopy experiments of correlated materials. The subpeaks in the local spectral function correspond to dispersive features in the momentum-resolved spectral function which are distinguishable from those for the quasiparticle peak and the Hubbard bands; see Ref. [4] for details. The enhancement of the subpeaks for larger $N$ is relevant to multiband materials. However, for materials in which the Hund’s coupling [22,23] is important, further analysis (beyond the scope of this work) would be needed to investigate how it affects the doublon-holon dynamics discussed here. Another promising class of systems for probing the effects of doublon-holon dynamics would be the cold atom systems studied in Refs. [24,25], where the SU($N$) Hubbard model has been realized with exact SU($N$) symmetry and tunable values of $N$.
